Luncheon meeting at the Institute, 4th December 1925, *the late Professor W. Myers being in the chair.*

RESEARCH AND MILL PERSONNEL

By Dr. J. C. Withers

I suppose it was inevitable that in the interesting course of mid-day conferences on factors which directly concern mill personnel, research should have been chosen as a subject for discussion. Why I should have been invited to take this particular topic is to me by no means so obvious, and I am not a little embarrassed to think I was rash enough to respond. Many here will expect me, perhaps, to deal with results which have been obtained by the Textile Research Associations, particularly that for the cotton industry, with which I am connected, and say how I imagine they may affect the staffing of mills and the welfare of the operatives; but I wish to speak to-day as a private member of the Textile Institute, and treat my subject in a broader way. In the first place, I want to attempt some explanation of what research *is*, and what are its results. My suspicion is that a good many persons in the textile industry regard it as a kind of magic worked in laboratories by "scientists." Research is not a magic, but a method or discipline. It consists in attacking problems by scientific method, which I would sum up in the words—*Prove all things; prove them one at a time*. First, the problem must be stated, and in many branches of the textile industry this is by no means easy. Then the causes which can make for different effects must be defined, and, finally, when studying one property, only one governing factor at a time must be allowed to vary unless the effects of other factors are so well proved that due corrections can be applied for them. For example, when comparing the spinning properties of two cottons, they must go through exactly the same opening treatments; when comparing two yarns, the testing conditions must be exactly the same; and when comparing similar processes or the effects of atmospheric and other conditions, the materials examined must be the same. Now what are the results of research? These can be divided usually into two groups—new facts about things, and new methods or processes.

Let me now give some examples of statements which are all too common in the textile literature to illustrate real deficiencies of research spirit or scientific method.

(1) In the production of yarns, there are the perennial debates, for example, as to the damage done by various opening processes, and as to whether the twist in ring yarns is inserted by the spindle or the traveller. Could not these questions be settled by experiment ?

(2) Sizing. An English authority declares that less than 8% of zinc chloride does more harm than good, whilst an American says 1% is adequate to prevent mildew. Are both correct ? Is the American letting his cloth reach the moisture regain which the English writer employs ?

(3) Again on sizing. Nearly all the books speak of the grave danger of tendering during singeing when certain chlorides are used in the size. This is said to be due to liberation of hydrochloric acid, but many authorities deny that the small quantities of chlorides present could, at the temperature employed, and in the brief time of action, give sufficient hydrochloric acid to cause any damage. What is the truth about this chloride "scare" ?

(4) A French authority has recently described an interesting case of supposed tendering of cloth when left in the hot drying-room above the calico printing machine. To his surprise, the cloth proved to be sound after conditioning. He had therefore an excellent opportunity to study the effect of temperature and humidity as factors influencing the strength of a fabric—a most interesting problem—and he performed some tests with his testing machine in the hot room. Unfortunately, the figures he publishes compare the breaking load of cloth at 85° C. and absolute dryness with the same at 4° C. and atmospheric humidity—*two* factors changed at a time instead of one. This renders his figures practically valueless.

So, coming to my argument, the first point I wish to make is that a study of the principles of research will show that there is a wide possibility for men in responsible positions in mills to become themselves real research workers. Many problems can be solved under works conditions if those in control will, to quote Huxley's letter to Charles Kingsley—"Sit down before fact as a little child, be prepared to give up every preconceived notion, and follow humbly wherever and to whatever abysses Nature leads."

It is generally recognised, however, that the solution of numerous trade problems demands such searching after fundamental facts with the aid of superior equipment that the establishment of centralised Industrial Research Institutes has been wise. Having discovered facts through the application of these unrivalled resources, the next step is to utilise them, and this is obviously where mill men are concerned. May I venture to assert that it is the *duty* of the practical man to endeavour to apply them. Discovered facts, rightly applied, inevitably make for better control of processes, which means quicker adaptation to new requirements than is achieved by relying solely on experience, and fewer faults. Surely these are desirable attainments in practice; and it would pay in the long run even supposing the mill should find it necessary to employ men trained in scientific method to interpret the results of research.

It is well known that many fundamental discoveries in science have required long and costly trials before they have been successfully woven into large scale practice. We have been reminded recently, for example, that the experimental work required for the development of the synthesis of Indigo into a successful commercial venture cost over one million pounds and twenty years of hard work. I am confident, however, that the textile industries will see a much more rapid application of the knowledge gained in their research institutes. Taking cotton, for example, I think it may rightly be claimed that the results of tests made in the Shirley Institute on high draft systems have already inspired confidence in a method of spinning to which Lancashire was averse, but which is bound to affect profoundly future lay-outs of mills. This confidence is reflected in the very rapid application of Lancashire brains to invention in this field, particularly during the past two years. Another group of researches at the Shirley Institute

which will, I think, find immediate application is that into the effect of over-bleaching on the properties of cotton cellulose. Methods have been described by which bleached cloth can be tested for the permanence of white or level dyeing qualities, and by which tendering can be detected in incipient stages. It has also been shown that many faults in bleaching, especially of goods with coloured stripes &c., are due to fluctuations in the degree of acidity or alkalinity of the chemic over a very small range, and that a great element of risk would therefore be avoided if means were available for checking the chemic periodically. These tests for bleaching efficiency and for controlling the chemic are well within the scope of a competent chemist, and it would seem therefore that at no distant date an efficient bleachery will add them to the routine of the works laboratory.

It is also significant, I think, that many recent discoveries in the field of finishing processes are based on conditions which are only secured within very narrow limits, demanding, therefore, rigid and expert control.

I now come to what may be, in some respects, the less obvious part of my argument, namely, the effect of the discovery of proved facts on the rank and file operative. I must decline to take up the question of possible effects on labour through the elimination of unnecessary processes or the betterment of working conditions, partly because these are so obvious and partly because they are controversial subjects. I want to state, however, that it is my conviction that greater knowledge about the properties of the things handled and the mechanism of the processes applied to them—the knowledge provided through research—will make for more interested, alert, and keen workpeople. Those of us who are new to Lancashire are astonished at the keenness for information on the part of those in the main body of the textile army, as revealed by their very numerous societies for the hearing of lectures and holding of technical discussions, and their appreciation when visiting our research laboratories. In my view this keenness is an invaluable asset to Lancashire. It should be fostered by bringing to the rank and file, as widely as possible, the results of scientific study. By feeding the desire for knowledge in this way, those "pessimistic reveries," to use the psychologist's term, which make for spoilt work and personal injuries will be greatly diminished.

Discussion

Mr. F. P. Slater said that Dr. Withers had stated very clearly what he considered was scientific method, but unfortunately in the past the Shirley Institute had at times been guilty of not carrying out the principles enunciated. Speaking as a scientist himself, he felt that research workers had only themselves to blame for a great deal of the mistrust with which the practical man regarded them. Much of the literature published with regard to research work would probably prove to be of ephemeral value, and it would be far better to wait until something really tangible and useful could be demonstrated before resorting to the letterpress. The suggestion to conduct an experiment in a mill under actual working conditions should be carefully considered before it was put into practice. One such experiment had been made by the Fine Cotton Spinners' Association, and had partially failed because it was not known at the time that the minder rattled the counterfaller in order to signal to the piecer at the other end of a long mule. Such matters might appear trivial, yet they meant sometimes all the difference between success and failure. The scientist was prone to study materials too much and his fellow-men too little. The strength of the textile industry in the future would depend upon the adaptability to changing conditions of the men who were maintaining it at its present level of efficiency, while the leaders who piloted them to success would be regarded deservedly as great men.

Mr. E. C. de Segundo wished, as an experimentalist, to take up the cudgels on behalf of the scientific man. Mr. Slater's criticism was severe, and correct to a certain extent, but there was also the point of view of the scientific man

himself to be considered. It was very seldom that the scientist was able to make his experiments under actual working conditions, and therefore it was unfair, when he had done the best he could with the means at his disposal, to state that his results were not borne out by experience in the mill. Personally, he was painfully aware of the unavoidable unreliability, from a practical point of view, of the results obtained by experimental work. A certain amount of compromise was always necessary, according to the governing factors of the situation. It was obviously not possible to adhere too closely to a determination arrived at in the laboratory, which might have been worked out to twelve places of decimals, under actual working conditions. He would like to ask whether, in connection with the process of cotton opening, the cotton hairs were actually damaged through being beaten by an iron bar.

Mr. F. P. Slater replied that by a special sub-microscopical method it was possible to detect the difference between a beaten and an unbeaten cotton hair.

Mr. de Segundo said that when observing the droppings from the scutching machine he noticed there was quite a large quantity of good cotton wasted and mixed with the trash and dirt. After investigation, he had come to the conclusion that once dirt was intermingled with cotton hairs in this way they were valueless, as it was almost impossible, by mechanical means, to segregate the contaminating material. Without desiring to criticise present-day methods, it might be a useful line of research to endeavour to modify the opening and scutching processes so as to avoid so much scutcher dropping.

Dr. Withers said that he had been careful to state that it was necessary to define what was meant by "damage." The Shirley Institute had obtained samples of cotton from a variety of opening processes in different mills. The tests showed that there was no appreciable alteration in staple length or in individual hair strength; whether there was any subtle damage which had not been detected was another question. Sweeping generalisations as to "damage" were not helpful.

Mr. Slater pointed out that after all cotton hairs did not remain merely cotton hairs, or even yarn. There was the problem of subsequent bad workmanship to reckon with. The whole of the processes of preparation and manufacture must stand or fall together.

Mr. de Segundo mentioned that 25 years ago he was a member of the Mechanical Engineers' Research Committee on Marine Engine Trials. Some broad-minded steamship owners very kindly permitted the Committee to carry out tests on certain steamers when on actual voyages. Thirty-six hour trials were carried out for the purpose of measuring the water consumption, and the results led to very useful innovations being made. If textile research workers could have a spinning mill placed at their disposal, they would speedily arrive at some good results from the practical man's point of view. The scientific man should be given a chance to apply his science to practice.

Mr. J. W. Baron did not think the mill was the proper place for the scientist, though he certainly ought to have access to it occasionally when necessary. What was required was to instil a spirit of research into the millworkers themselves, so that they could make their own observations and reports. A mass of information could thus be collected which would materially assist the scientist in the solution of the problems with which he was confronted.

Mr. Slater thought that if the scientific man went into the mill he was bound to be a nuisance to the operatives, who would regard him as interfering with their bread and butter. If the business man would compensate the operative for any loss of working time, then some good result might be obtained.

Mr. W. Bailey said that he had conducted a large number of experiments over a number of years, principally in connection with textile machinery. Results obtained under engineering works conditions were apt to become considerably

modified in actual mill practice. He was very interested in the remark of Dr. Withers as to proving whether the spindle or the traveller put in the twist with the ring-spinning frame. This had been a bone of contention not only with cotton spinning people but with students for many decades.

Mr. T. F. Robinson thought that theory was of little value without practical demonstration, and there should be co-operation between the scientist and the practical men of all branches of the textile industry. The suggestions made by Dr. Withers were of a distinctly practical character, and he felt that this paper marked a definite step towards breaking down the barrier between the scientists and the practical men. The Textile Institute through this lecture would make a valuable contribution to the task of bringing about the essential co-operation of theory and practice.

Mr. F. Nasmyth moved a vote of thanks to Dr. Withers for his interesting paper, which had certainly opened a new field for discussion. Personally, he had hoped for a little more elucidation of the type of personnel which would be necessary for the mill of the future. A change was impending, and yet they were all a little uncertain as to its precise trend. There should be certainly some liaison between the students of the Colleges of Technology and Research Departments such as the Shirley Institute. Immediate results should not be looked for from research associations, as for the demonstration of useful methods time and experience were necessary. Nevertheless, they were entitled to look to research associations for some sort of lead and guidance to the Colleges of Technology as to what direction the training of students should take. The practical man in the Lancashire mill was very conservative, and thought he knew a great deal more than the scientist. However, they must not think of the mills of to-day, but of the mills of the future. The Textile Institute was a means whereby a young technical student would be enabled to climb the ladder of success, and the recognition of his technical qualifications, which it could confer upon him by virtue of the provisions of its charter, would prove of inestimable value.

Mr. J. Crompton seconded the vote of thanks. He thought the relationship between industry and research was happily explained in the paper. The meeting had been a very profitable one, and he could not help coming to the conclusion that out of such gatherings something great and wonderful was bound to materialise.

Dr. Withers briefly responded to the vote of thanks, and the proceedings closed.

London Section

Discussion Meeting in the Institute's Rooms, 38 Bloomsbury Square W.C.1, 9th December 1925, Mr. A. R. Down in the chair.

THE SPECIFICATION OF TEXTILES FOR CONTRACT

After being introduced by the Chairman, the lecturer, Mr. H. B. Heylin, said his remarks would principally refer to textiles woven of cotton, linen, woollen, jute, and hemp, which were by no means obsolete despite the advent of a "silky cellulose product of uncertain nomenclature." By "specification" he meant the furnishing of all those particulars which defined the construction of a fabric. Advertisement and shop-window descriptions might be considered as specifications of a crude type when they implied in a general way the quality of the material or article for sale. It was not uncommon, unfortunately, for customers to be deceived by a shop assistant, either deliberately or unconsciously, into buying textile materials other than those they required; while a smart salesman may succeed in impressing a departmental buyer with such terms as "strong," "durable," "tenacious," "well-milled," "well-shrunk," "pure," "waterproofed," thereby effecting a sale without regard to the facts of the case. These, however, were minor aspects of the question of fabric specification which he would deal with in relation to the supply for the wholesale market, herein the product must be standardised in quality and purity. Though those who handle textiles constantly may be able to convey such a definite idea of their requirements that the "making particulars" can be planned out by the manufacturer himself yet under such circumstances it would be surprising if two manufacturers succeeded in producing fabrics exactly the same in all respects. On the contrary it is possible for a person possessed of accurate knowledge to convey a specification to any reliable manufacturer and in every case to receive his fabric with very little variation. In reputable textile circles where buyer and seller, merchant and manufacturer understand each other, large quantities of goods can be ordered against "a quality pattern" and the manufacturer will ascertain the "making particulars" by cloth analysis. Details of width, length, finish, make-up, &c., would be supplied on the order sheet, and tolerances would be allowed according to the customs of the trade or to recognised standards. Sometimes a merchant or middleman supplies full "making particulars" and the manufacturer has no need to resort to cloth analysis; while in exceptional cases all the warp and weft yarns required are supplied with the full specification by the merchant and then the manufacturer will probably weave the cloth on commission. Thus, said Mr. Heylin, where properly qualified buyers and sellers are concerned confidence is engendered and the satisfactory working of a contract is ensured. It is the exception rather than the rule for textile goods to be delivered not up to standard in regard to quality and general make. The large majority of spinners, doublers, manufacturers, dyers, and finishers have reputations to uphold and whose aim is to give the best of service to the textile trade.

The lecturer then proceeded to deal with the issue of specifications by authorities, organisations, Government departments, &c., who are buyers of large quantities of textile goods. How the lack of technical knowledge and of the conventionalities of the industry often resulted in the laying down of conditions more calculated to hinder than to help the manufacturers and to impair the efficiency of the goods was carefully explained and an outline of what might be considered a reasonable method of framing such specifications was given by the lecturer. In the event of controversy as to the quality or standard of a fabric it is essential that the matter should be referred to the decision of a person well qualified by training and experience to give judgment. To such persons, who may themselves be said to come up to a high standard specification, there should be awarded the hall mark of their profession. Their title to such distinction

can only be measured by their mental training and practical industrial knowledge. The degree of technological qualification to be demanded by the Textile Institute now that its Charter was an accomplished fact—must be of the highest, and Mr. Heylin intimated that all the world awaits with interest an announcement as to which members were adjudged worthy of the new distinction. As a foundation member, he hoped to see evidence of a high standard and of early progress.

Discussion

The Chairman said he found that practically the whole of the shipping buying was done on sets of samples sent out or on samples carried by travellers. He did not think they would find many buyers in London with the necessary technical education for drawing up detailed specifications for a manufacturer. That was what the Textile Institute in London were out to correct. They really wanted to reach 300 members at least by next year, and by then they would have funds enough to launch out and perhaps interest education authorities in London to give classes to educate young persons as to how cloths were made.

Mr. E. B. Fry said that it was of great importance that specifications should be given in a proper way, as when they were given in a haphazard manner all sorts of variations could creep in. He thought that specifications should be fairly complete, otherwise there would be a great deal of difficulty in interpreting them.

Mr. C. Coleing asked if Mr. Heylin thought that shippers and other big buyers of fabrics should possess qualified officials who would be able to supply the form of specification he had described, because speaking from his own knowledge of the retail and shipping business, both of which he had been interested in, he had never heard of anybody doing anything of the sort in a technical manner. He rather gathered that Mr. Heylin indicated that the specifications prepared by public bodies of this country were in need of overhauling. Was that so, and in what connection did he think the Textile Institute could take the matter up and deal with it ?

A member of the audience asked whether one ought to mention the condition of humidity required at the time of the strength test.

Mr. Heylin said that from one point of view a sample acted as a specification, and that was the way a tremendous amount of business was done. On the exchanges in the North, between man and man, a certain amount of confidence existed. He believed that many shipping offices had technical experts who examined cloth. He would be very bold indeed if he were to tell them how a specification should be made, because there were many ways according to the different view-points. What one might think was not essential, another might. It was a matter where the Textile Institute with its body of qualified men could sit round a table and do something perhaps in a few hours that some other bodies could not do in as many years. As to what should be included in a specification no one man could say that it must be such a percentage of this or of that without deviating one iota. There had to be a little elasticity. With regard to allowance for moisture, it was far better to ascertain what that should be and lay down reasonable rules so far as the moisture in yarn was concerned, but when they got to the woven fabrics they were up against many difficulties. The Textile Institute would be the best authority for making out specifications for guiding purposes.

Replying to a member present, Mr. Heylin said he was not against a strength test but it should not be made a primary feature.

Mr. Fry asked if putting the strength test in a subordinate position did not open the way for the manufacturer to use slightly inferior material. If a man wanted to reject he could find some other ground than a strength test.

A visitor thought that Mr. Heylin had brought out an important point which emphasised the necessity for the Institute taking up the question of specifications.

Mr. J. Howard said he was entirely at variance with Mr. Heylin on the strength test. He defied him or anybody else to settle quality without a strength test. It was such a remarkable factor in quality that no manufacturer dared use yarn

until he tested it. No one could tell the quality of yarn or length of fibre without putting it on a testing machine. The question of humidity must be left to experts alone. The testing machine used by men who were always at it was a much more accurate thing than people believed. The last thing he would take out of a specification was the breaking strain.

Mr. Heylin said he did not definitely say that the strength test was no use; it was very useful but he did not look upon it as the primary factor. He did not think it would be wise for any manufacturer to be without the single thread testing machine, but when threads were put into cloth there were further conditions to be considered. Manufacturers would aim to satisfy the strength test, if that was made a paramount feature in the specification.

Mr. Howard said if the actual strength required was not put in the specification, the manufacturer could make the cloth to specification without making it to quality. Given a satisfactory weight it was the best cloth that pulled to the best strength.

The Chairman asked the Secretary of the London Section to answer a visitor who asked whether the Textile Institute would not consider promoting the formation of a Testing House in London.

Mr. Featherstone stated that this question had been very seriously considered by the London Section Committee; that a proposal to form such a Testing House had met with the warm approval of many trading organisations, but that no promise of any financial support whatever could be obtained. The Committee therefore had been compelled to let the matter drop.

Mr. Heylin thought the discussion showed that there was plenty of room for the Textile Institute.

Mr. Coleing moved a hearty vote of thanks to the lecturer, which was seconded by Mr. E. B. Fry, and carried unanimously.

NOTES AND NOTICES

Annual Election of Vice-Presidents and Council

The arrangements with regard to the annual election of Vice-Presidents and Council of the Institute are considerably changed for the years 1926 and 1927, as a result of the reconstitution of the organisation under the Royal Charter and new Bye-laws. Ordinarily, at least three Vice-Presidents and ten Councillors are due to retire and are eligible for re-election unless disqualified by non-attendance or other reason mentioned in the Bye-laws. The three Vice-Presidents and ten Councillors to retire in the usual course of events would be those who had been longest in office, but for 1926 and 1927 the Council have to decide the retirements. At the Council Meeting on Wednesday, 20th January, the decision arrived at by Council creates three Vice-Presidential vacancies and ten Council vacancies. Nominations are now to be invited and it has been decided to issue a special nomination form direct to members. This year there will be ten absolute vacancies for the Council owing to several cases of ineligibility and retirements for other reasons. On receipt of nomination form, members are invited therefore to bestir themselves in this highly important matter of nomination for election at next Annual General Meeting, which is due to take place at the Institute at Manchester on Wednesday, 21st April. The time for return of nominations is stated on the form, and it is important to note that additional nomination forms may be secured on request to the General Secretary.

The Institute Diplomas

Notwithstanding the fact that no announcements are yet available in regard to the award of the new Diplomas of the Institute (Fellowships and Associateships), the statement may be now made that the publication of the first list of

successful applicants may be expected to be published in an early issue of this *Journal*. The fact is that applications have come to hand in such considerable number that the Selection Committee, in spite of unusually prolonged meetings and deliberations, is not able to keep pace with the immediate demand. Applications for the most part require extended consideration, and it is the rule that before definite recommendations are made to Council, the Committee's own decisions are subject to confirmation at a subsequent meeting. The General Secretary of the Institute has received many inquiries from applicants as to progress in regard to applications. All applicants should note that no real delay is permitted, but that the formidable task which confronts the Committee involves a period of time which cannot be reduced owing to the sheer force of the circumstance of numbers of applications to be dealt with. Certificates have now passed the stage of printer's proof, and announcement of the decisions of the Committee and confirmation by Council is being expedited to the utmost extent.

Exhibition of Knitted Fabrics and Yarns

In connection with the Lancashire Section of the Institute, it is proposed to hold an Exhibition of Knitted Fabrics, and Novelty Yarns for Hosiery or Knitted Fabrics, on the 18th, 19th, and 20th March, at the Institute Headquarters at Manchester. The Council has given special sanction to the Lancashire Section Committee to embrace the whole field of membership of the Institute in respect of the organisation of the fixture and invitations to exhibit. Exhibitors will be limited, except in the possible case of technical institutions, to firms directly or indirectly represented in membership of the Institute. Any member who can assist either by suggestion to the organisers or by securing an exhibit should communicate with the General Secretary at the earliest possible date. It is felt that a stage has now been reached in regard to knitted fabrics and yarns when a really representative collection should be got together. It is proposed a discussion meeting on either the first or second day of the exhibition, and the British Association of Textile Mill Managers will be specially invited to take part in the meeting. The organisation named invited the Lancashire Section members of the Institute to their meeting on Saturday, 23rd January, when a lecture on "Yarns for the Hosiery Trade" was contributed by Messrs. J. Chamberlain and J. T. Stokes, of Leicester. Apart from the circular letter which is being issued to members generally, the General Secretary would be grateful for immediate proposals to exhibit on the part of any firm connected with membership of the Institute.

Annual Balance Sheet and Accounts

A draft of the Balance Sheet and Accounts for 1925 was presented to Council at its meeting on 20th January, and were approved subject to certain adjustments in the way of special assignment of revenue from the Foundation Fund investments. By comparison with the record for the previous year, the accounts for 1925 show a decided improvement in the financial position of the Institute. In place of the small deficit brought forward from 1924, there is a small excess of income over expenditure for 1925. It will be recalled, of course, that the small deficit brought forward at the end of 1924 did not represent the entire deficit for the year, because previous surplus had also been absorbed. The membership subscription revenue shows a considerable improvement, whilst not only has economy been secured in regard to the *Journal*, but substantial improvement of revenue has materially helped the general financial situation. The restoration of the condition of the finances which prevailed at the end of 1923 is not yet effected, but the outlook is encouraging and it is confidently hoped that the previously existing surplus will eventually be re-established. The fact should be stated that whilst additions to membership have latterly

accrued at an unprecedented rate, nevertheless there have been quite a considerable number of withdrawals. Notwithstanding that the former outpace the latter, yet the Council is most anxious that no effort should be spared in promoting increase of membership, and all existing members are invited to assist in this direction during the current year.

Competition in Novelty and Folded Yarns

The Institute's Committee in charge of the Crompton Prize Fund Scheme, under which prizes are offered annually in regard to design and structure of woven fabrics, has this year embarked upon an additional enterprise. On the suggestion of the Committee, the Council of the Institute agreed that donations should be invited in order that prizes may be offered for special yarns. Messrs. R. Greg & Co. Ltd. (South Reddish, Stockport), have kindly consented to contribute £25 per annum for three years. The Crompton Scheme Committee has accordingly prepared a competition for the current year, the object of which is to encourage effort on the part of students in the Spinning Departments of Technical Colleges and Schools. Prizes of £8 and £4 will be offered in each of two classes—for Novelty Folded Yarns, and Folded Yarns respectively. Details and conditions are attached to the general prospectus, the issue of which is expected to take place before the end of January.

Membership Certificate

An interesting case of recovery of personal effects inadvertently left in a compartment of a continental railway train has recently come to our notice. A member of this Institute recently left a pocket wallet in a train between Paris and a Cross-channel seaport. Fortunately for the owner, the wallet contained a certificate of membership of the Institute. The result was that a communication was received at the Institute intimating that the wallet had been found. The member in question was notified and, in the course of a few days, we received a grateful letter from the member stating that the wallet had been returned to him, with the contents complete.

Section Activities

In addition to the Exhibition of Knitted Fabrics and Hosiery Yarns, of which notice is given above, the Lancashire Section Committee has arranged a meeting at the Institute, Manchester, on 12th February, at 4 p.m. Thereat two papers will be read and it is hoped discussion of a most valuable kind will afterwards take place. The papers in question are—

"The Effect of Sizes on the Elastic Behaviour of Flax Yarns," by Mr. J. A. Matthew (Belfast).

"The Detection and Estimation of Glycerol in Cotton Cloths and Sized Yarns," by Mr. George Smith (Great Harwood).

In the case of the second paper, the author is unfortunately unable to be present to read his contribution, and arrangements have been made for a member of the staff of the British Cotton Industry Research Association to do so in his stead. These papers will subsequently appear in the *Journal*, together with a report of the discussion. The Yorkshire Section Committee will have before it at an early date the proposal to arrange for a similar meeting, and three papers, one by Mr. W. Rhys-Davies and the other two by members of the staff of the British Research Association for the Woollen and Worsted Industries, have been submitted as especially suitable for presentation to the members of the Section. This marks the onset of a definite policy in respect to the reading of papers, and it is hoped that in all cases adequate support will be given to the efforts of the Section Committees.

COMMUNICATION

To the Editor

Sir,—We have recently had experience of grey mixture pieces, the black component of which was dyed with Azo Chrome Blacks of the Eriochrome Black type, turning up after finishing with a slight yellow cast on the white wool. This yellow cast spoils the clear blue tone of the finished goods, and we considered it advisable in the interests of trade generally, that the cause of this fault should be discovered, and remedies applied.

As a result of a considerable amount of work done in this laboratory, and also on a practical scale, we are now able to state that the fault is due to free sodium carbonate being left in the goods after scouring and milling, and only occurs when such is the case. We have further proved that the fault is increased where a very greasy wool has been dyed, and the grease has not been entirely removed in the dyeing process. Grease, however, is not the cause of the fault, but merely an assisting factor.

The fault can be remedied—

(1) By thorough washing off after milling.

(2) By adding a little of any acid to the washing-off liquor.

Acetic acid, however, is not advisable since its sodium salt gives an alkaline reaction, and we recommend formic acid as the most suitable on account of its strength, and the fact that any slight excess volatilises on drying.

In cases where the handle of the goods may be impaired by this final treatment, the excess of acid should be again neutralised with a little ammonia. This, however, will not be necessary except under the most extraordinary conditions.

We should be obliged if you would publish this communication, as we consider these facts should be widely known, particularly among finishers.

F. Goodall, M.Sc., *Chemist.*

REVIEWS

Die Schwefelfarbstoffe ihre Herstellung und Verwendung. By Dr. Otto Lange. Otto Spamer, Leipzig (Zweite auflage, 1925, 25 Gm.)

"If an inquiry thus carefully conducted should fail at the last of discovering the truth, it may answer an end as useful, in discovering to us the weakness of our understanding. If it does not make us knowing, it may make us modest. If it does not preserve us from error, it may at least from the spirit of error, and may make us cautious of pronouncing with positiveness and with haste when so much labour may end in so much uncertainty."—*Edmund Burke.*

Fourteen years have passed since the appearance of the first edition of this book. During this time there has been little or no advance in our knowledge of sulphur colours. No new colours of note have been prepared and no advance has been made through the mysterious hinterland of darkness with which their constitution is still, for the most part, enshrouded. The only definite crystalline sulphur colour derivative is still the bisulphite compound of Immedial Reinblau, and the only well-substantiated grouping is the thiazine ring; but how it is figured in the molecule we are still in ignorance. Dr. Lange himself regretfully labels the period sterile. This absence of advance (even taking the effects of the war into consideration) forms a most remarkable period in scientific and industrial chemistry. When we consider the enormous stride taken from the primitive sulphur colours of 1895 to the bright shades from esoteric combinations of 1910, the contrast is strangely marked. It was during this fifteen years that the majority of the sulphur colour patents were granted and countless workers in the laboratories of the German colour firms feverishly mined the new ore. Then quite suddenly a great silence . . . . as though the rich seam had suddenly petered out. Shall we see great discoveries in the future of this branch of knowledge ? It is hard to prophesy. It may be that we shall yet see chlorine fast sulphur blacks which will be cheap enough to supplant developed aniline blacks. Perhaps . . . .

In general terms this book is a reprint of the first edition with some omissions. We think it has suffered by this cutting. Some chapters (e.g., Anorganische Ausgangsmaterialien:Schewefelung organischer Körper) of the first edition have been removed bodily, and one at least (Organische Ausgangsmaterialien) has been cut to a quarter of its size—although we are consoled by the author who directs us to find the remainder in another of his text books (*Die Zwischenprodukte der Teerfarbenfabrikation*, Leipzig, 1921). The present edition is still divided into two main parts dealing respectively with sulphur colours *per se* and with their application. The first part contains (among many others) a precise account of work done on theories of structure, which is a miracle of compression. Those chapters dealing with the very great variety of starting materials and intermediate compounds are complete and thorough, with the exception noted above. At the end of the volume will be found extracts from some 747 patents which comprise the majority of the literature of the subject. The second part of the book is concerned with the application of sulphur colours for dyeing as well as for textile printing. A comprehensive account is given of colour testing, dyeing, and development in every one of their numerous phases, as well as diagrams of the most widely used dyeing machines. The chapter dealing with cotton printing of sulphur colours develops the subject logically and includes diagrams of machines and clear descriptions of a variety of processes.

The first edition suffered from a lack of satisfactory indexes—almost a unique lacuna in a German scientific work. We regret very much that the second edition errs still further in the same direction. The admirable cross reference system for patent numbers (based on that initiated in Friedländer's Teerfarbenfabrikation) has been suppressed entirely. This omission detracts seriously from the use of this edition as a work of reference. Further, there is a crying need for a special index for trade names of colours and we strongly urge the publishers to consider this when preparing a third edition. These trade names form the most practical means of referring to a given colour and they occur in the most unexpected places. A search for a desired name in the present edition is likely to be a most laborious affair. The addition of such an index together with a complete subject index would add much to the value of the book. This edition in its precise completeness will be found a very valuable equipment for those engaged in the industry. The colour manufacturer as well as the dyer will find all the information he needs here, and the work should make in addition a special appeal to those imaginative investigators whose thirst for problems worthy of their steel leads them into strange places. R.W.P.

Trade Stability and how to obtain it. Sir Charles Macara. Sherratt and Hughes, Manchester.

This book is a collection of the writings of Sir Charles Macara upon the question of Cotton Control. There is very little in it that appears for the first time; and the purpose of the volume would appear to be the bringing together and classification under chapter headings of a number of newspaper articles, letters, and opinions bearing upon the problems with which the Provisional Emergency Cotton Committee is concerned. The character of its matter necessarily introduces into the book a certain lack of cohesion; but any person desiring to acquaint himself with the case for Control will find here all he requires.

Perhaps the details of the case are not so well known as they ought to be. Controversy has necessarily introduced irrelevancies and personal expressions of opinion which tend somewhat to cloud the issue. Sir Charles' thesis, in brief, is as follows. Over a period of thirty years the spinning section of the cotton trade, or more precisely the American section, has not paid, on the average, more than 5 per cent. to its shareholders; and the value even of this return must be discounted for its variable and uncertain character from year to year. This small return is due (*a*) to lack of co-ordination among spinners, and (*b*) to their large measure of dependence upon one source of raw material supplies. The expedient of organised short-time which the Federation of Master Cotton Spinners has from time to time adopted, is not rigidly observed by a certain number of mills; and in any case is not able to function adequately, since there is neither a statistical measure of the exact extent of the need for it, nor do the rules of the Federation allow of its being recommended to members except on the basis of an 80 per cent. vote in its favour, which will be given only in cases of extreme

and general depression. The proposed Control Board is relied upon to secure the requisite data as to production, consumption, and stocks of yarn; and sanctions for the observance of the recommendations of the controlling authority are to be devised in conjunction with the operatives' unions, which undoubtedly have as close an interest in the well-being of the trade as the shareholders of the capital invested in it. The sanction proposed is the withdrawal of labour from the mills of recalcitrant firms.

Such is the argument. The outstanding proposals are those regarding the collection of statistical data and the introduction of sanctions. The first is one that must soon pass beyond its present stage. The general tendency in modern industry is for more light on these matters which have hitherto been regarded as strictly the concern of individuals. This change of attitude is particularly noticeable in the United States, where it has been realised that knowledge, even of the worst, is better than struggling in the dark; that with it readjustment of production to demand, over a period, is much more exact and much more prompt. It is better that everyone should know the worst, and how bad it is; they can then decide what to do about it. Sir Charles goes no farther than to propose that the controlling authority should have possession of this data. The Americans publish it for everyone to see. As to the second proposal, it is simply an elaboration of the short-time policy of the Federation on a more effective basis. With the latter it shares certain advantages and disadvantages; it might, for instance, be used to bolster up the inflated capitals of certain mills. But there is a defect, inherent in all authority, that the Control would introduce. This is the risk of injustice being done in individual cases; orders would necessarily have to be general and to ignore all except wide classifications of firms. "American Section" is a term embracing firms working for a wide variety of markets; and presumably that amount of individual discretion allowed—by conscience—under the present short-time scheme would be removed. From the point of view of the trade in general, there is another objection. The aim of "control" is what the name implies, control of supply, restriction of output; it is the short for "monopolistic control." It is the substitution of common policy, backed by authority, for spontaneity in business relationships; and before any such step is taken the consequences of it must be scrutinised most carefully. Nevertheless, the proposal is a serious one and deserves serious consideration, for which this book affords opportunity.

G.H.M.

GENERAL ITEMS AND REPORTS

Advisory Council—Department of Scientific and Industrial Research

The Secretary of the Department makes the following announcement—"Dr. George Christopher Clayton, C.B.E., M.P., and Professor Henry Cort Harold Carpenter, F.R.S., have been appointed by Order of Council, dated 16th September 1925, to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research." Professor Carpenter occupies the Chair of Metallurgy in the Royal School of Mines, South Kensington, and is well known for his researches on metals and alloys. Dr. Clayton, who represents Widnes in the House of Commons, is a Ph.D. of Heidleberg, and a Director of the United Alkali Company.

Some Diseases of Cotton as seen in the Plantations

Before the Manchester Literary and Philosophical Society on 8th December 1925, Dr. W. Robinson read a paper upon the above subject, Dr. H. Levinstein, President of the Society, being in the chair. Dr. Robinson said* that in order to facilitate research work being carried out in the University of Manchester, for the Empire Cotton Growing Corporation, a visit was paid to some of the Cotton States of America in the summer of 1924.

The diseases of cotton described were observed in the plantations of North and South Carolina. In that season, according to recently published estimates by the U.S. Department of Agriculture, fungal and bacterial diseases of cotton reduced the crop in the U.S.A. by one million, nine hundred thousand bales.

*Report furnished by the Secretary, Manchester Literary and Philosophical Society.

The extent of these losses in what was a relatively favourable season for cotton growing indicates the importance of these diseases.

In the United States some of the diseases are more important than others, but, at the present time, all of them may be important to this country in view of the considerable extension of cotton-growing in progress in various parts of the British Empire. In some of these countries a new crop plant is being introduced; we have little knowledge how it will react to its new environment and we do not know what diseases will appear. It is certain, however, that some diseases will occur, and it is well known that a disease which is relatively harmless in one country may become destructive in another.

This may be illustrated by some of the diseases seen in the United States. *Bacterium malvacearum* causes the angular leaf spot and a boll disease on Upland varieties of cotton (*Gossypium hirsutum*), the leaves and bolls usually being the only parts of the plant affected. The Sea Island and Egyptian varieties of cotton (*G. barbadense* and *G. peruvianum*) are much more susceptible to the attacks of the organism which also affects the leaf stalks and branches, causing the "Black arm" form of disease. This "Black arm" disease is already causing serious concern in the Sudan on Egyptian cotton, although in Egypt, presumably on account of the different climatic conditions, it is not troublesome. It is now known that infection may be carried on the seed, and seed-disinfection has proved successful in preventing the disease in the United States.

Again in the U.S.A. several root-diseases of cotton occur. Of these the Texas root rot (Ozonium) and the wilt disease caused by *Fusarium vasinfectum* are of most importance. In the latter case the disease was studied in South Carolina on badly infected soils. The fungus present in the soil passes into the conducting tissues of the plant and excreting poisonous substances leads to dwarfing, wilting, and killing of the whole plant. In the Sudan a root-disease (the Tokar root-rot), undoubtedly different from the Fusarium wilt or Texas root-rot but capable of stunting and killing the plant by progressive infection, is also causing trouble. Work at present in progress on this disease should ultimately determine its cause and probably provide for its control.

Diseases of the immature or opened bolls are commonly caused in the U.S.A. by *Glomerella gossypii* (anthracnose disease), *Fusarium, Diplodia*, and by *Bacterium malvacearum*. The cotton lint is destroyed, weakened, or discoloured by such organisms. Similar boll diseases occur wherever cotton is grown, and recent studies by Mr. R. W. Marsh on discoloured cotton from Nyasaland have shown that the yellow discoloration is due to a species of *Nemataspora*, a fungus which in the West Indies has been shown by Nowell to be inoculated into the bolls by cotton stainer bugs which puncture the bolls as they feed. Stainer bugs were observed feeding on cotton bolls in South Carolina, but the *Nemataspora* fungus is not up to the present known to cause disease of cotton in the U.S.A. Other diseases of cotton studied were those caused by species of *Alternaria* and *Ascochyta gossypii*. These have not hitherto been of serious consequence in the United States, but the latter is now spreading, and both diseases may prove much more harmful in other countries.

Of the diseases to which reference has been made several have as yet been imperfectly studied, and only by extended work on such diseases and on the organisms responsible for them will it be possible for the growers and plant pathologists in cotton countries to guard against outbreaks of disease and to devise satisfactory means of control when such outbreaks occur.

Woollen Spinning

Mr. W. O. R. Holton, lecturing on "Woollen Spinning" before the Bradford Textile Society on Monday, 7th December, 1925, said that the making of a good woollen cloth required a good woollen yarn, and the problem of the woollen manufacturer was to make a blend which would spin well and produce a satisfactory thread at the required cost. Raw materials must be carefully selected for blending with a view to producing the "finish" effect required by customers and to producing a sound well-blended woollen yarn. The lower the cloth, the more essential this was. The manufacturer must master all the different combinations which could be made by the use of long coarse wools, cross-bred, fine cross-breds, merinos, wastes from the worsted section, mungoes, and shoddies of all descriptions. Machinery must be well built on proper lines in order to turn

out work of good quality in sufficient quantities to enable the manufacturer to compete; and the lower the quality of material used, the more efficient and up-to-date the machinery must be. A good spinning blend could be completely spoilt by bad blending or uneven oiling. The carding process was recognised as the chief factor in the successful spinning of woollen yarns. The engine was somewhat similar to that used in the Bradford trade, but the card clothing had to be of quite a different kind in order to card and open out the very short materials used, whilst it must be more flexible and pliant. The self-acting woollen mule was easily the most complicated and wonderfully constructed machine employed in woollen cloth manufacture. The scroll was described as the soul or principle of woollen spinning. In the woollen process the human element was more largely called upon than in cotton or worsted spinning, and the faculties of observation, intuition, and quick decision were essential. One set of rollers only was used, and the purpose of it was simply to feed and hold fast the condenser threads or slubbing. When the rollers stopped, the mule carriage and spindles were about half-way out, and as the mule continued to get further away, the spindles imparted the requisite amount of twine and draft, and thus produced a frizzier yarn than the roller drawing process. The working of the scroll and twine called for very precise judgment even on the part of the most capable spinners. The art of spinning consisted of first obtaining the ideal thickness of condenser thread, which was not a fixed quantity proportional to the thickness of the yarn required, but varied with the qualities of the material of which the blend was composed and the type of yarn required. Then followed the regulation of (1) The speed at which the condenser threads passed through the rollers, and therefore the precise time at which these rollers were stopped; (2) the speed and regulation of the mule coming out; and (3) the speed at which the spindles were run. If the thread were drawn too tightly in the early part of the draw, the resultant thread would be uneven and tight. It was highly necessary that strict attention be given to the human element. When everything had been done in the way of good blending and an efficient foreman had exerted all his skill, the keeping of the yarn up to quality depended a great deal upon piecers in the mule gate. M.

Exhibition of British Artificial Silk Goods

The Drapers' Organiser is arranging the first exhibition of its kind to be held at Holland Park Hall, London W11, from 19th to 24th April. Exhibits will consist of the products of manufacturers, dyers, and finishers of yarns and fabrics made either wholly or in part of artificial silk. The artificial silk industry will be revealed from the yarn production to the finished and dyed fabrics, and thus will be indicated in the fullest possible way all sources of supply. In addition, daily mannequin parades will be held to display gowns in artificial silk or artificial silk unions designed by the leading costumiers. The trade alone will be admitted during Monday, 19th April to Friday, 23rd April, but on Saturday, 24th April, the general public is to be admitted. There is evidence that this exhibition will be a most successful venture.

Competition of Industrial Designs

The Royal Society of Arts announce their annual competition in various classes of industrial designs to be held in June next. Particulars as to classes of candidates and methods of entry, preparation of designs, &c., are ready and may be obtained from the Secretary, John Street, Adelphi, London, W.C.2. Of particular interest are the competitions in Textiles, in which the subjects of competitions are designs for the following—

Sub-section (1) Floor Coverings, including Carpets and Rugs, Linoleum, and Floor Cloths.

,, (2) Woven Fabrics for Furniture and Decoration, including Tapestries, Damasks, Brocades, Figured Velvets, Table Damasks, and Moquettes.

,, (3) Printed Fabrics for Furniture and Decoration.

,, (4) Printed and Woven Fabrics for Dress, including Brocades, Fancy Dress Fabrics, Handkerchiefs, Tie Silks, Mufflers, Ribbons, and other narrow goods.

Sub-section (5) Machine-made Lace, Lace Curtains, and Embroidery.
,, (6) Miscellaneous, including Hand-made Lace, Embroidery, and Open Work, Bedspreads, Cushion Squares, Tea Cosies, Batiks, &c.

Candidates may submit designs for any or all of the items in any or all of the foregoing sub-sections. The prizes offered are sufficiently attractive and consist of one or more Travelling Scholarships to candidates of outstanding ability. In 1925 one such Scholarship of £150 was awarded. In addition the Judges are empowered to award money prizes up to £10 10s. each for designs in any of the sub-sections mentioned above.

Dyestuffs (Import Regulation) Act 1920

The following statement relating to applications for licenses under the Dyestuffs (Import Regulation) Act 1920, made during November and December, has been furnished to the Board of Trade by the Dyestuffs Advisory Licensing Committee.

The total number of applications received during the month of November was 682, of which 579 were from merchants or importers. To these should be added 34 cases outstanding on the 31st October, making a total for the month of 716. These were dealt with as follows—

Granted, 597; referred to British makers of similar products, 76; referred to Reparation supplies available, 5; outstanding on 30th November 1925, 38. Of the total of 716 applications received, 608, or 85%, were dealt with within seven days of receipt.

The total number of applications received during the month of December was 571, of which 487 were from merchants or importers. To these should be added 38 cases outstanding on the 30th November, making a total for the month of 609. These were dealt with as follows—

Granted, 485; referred to British makers of similar products, 86; referred to Reparation supplies available, 14; outstanding on 31st December, 1925, 24. Of the total of 609 applications received, 534, or 88%, were dealt with within seven days of receipt.

THE JOURNAL OF THE TEXTILE INSTITUTE

Vol. XVII FEBRUARY 1926 No. 2

PROCEEDINGS

CHARTER OF THE TEXTILE INSTITUTE CELEBRATION PROCEEDINGS AT BRADFORD

In celebration of the grant of a Royal Charter of Incorporation to the Institute, a luncheon was held at the Midland Hotel, Bradford, on Monday, 25th January, 1926, at which Lord Emmott was the principal guest. The President of the Institute (Mr. John Emsley) occupied the chair, and amongst those present were—The Lord Mayor of Bradford (Ald. J. Stringer), the Mayor of Keighley (Ald. Arthur Smith), the Mayor of Morley (Councillor E. Kirby), the Mayor of Pudsey (Mr. Edward J. Byrd), the Mayor of Wakefield (Mr. Chas. Mellor), the Mayor of Brighouse (Ald. A. M. Denham), the Mayor of Pontefract (Councillor J. Hutchinson), and the Mayor of Todmorden (Mr. Wilson Greenwood); Lieut.-Col. A. Gadie, M.P. (Central Bradford), Mr. Eugene Ramsden, M.P. (North Bradford), Ald. T. D. Fenby, M.P. (East Bradford), Mr. T. W. Stamford, M.P. (N.W. Leeds), Mr. Ben Riley, M.P. (Dewsbury), Mr. W. Forrest, M.P. (Batley and Morley), Mr. J. Potts, M.P. (Barnsley); Mr. J. R. Pollit and Mr. Douglas Hamilton (Vice-presidents, Bradford Chamber of Commerce); Mr. F. L. Moorhouse (President, Huddersfield Chamber of Commerce); Mr. J. J. Stubley (President, Batley Chamber of Commerce); Mr. Howard Clay (Halifax Chamber of Commerce); Mr. Thos. R. Taylor (Cleckheaton and Heckmondwike Chamber of Commerce); and Mr. W. Muir Oddie (Ossett Chamber of Commerce); Mr. H. Sutcliffe Smith (Chairman, Colour Users' Association); Mr. B. Parkinson (President, British Wool Federation); Mr. Walter Andrews (Vice-president, Federation of British Industries); Sir Donald Horsfall, Sir William Bulmer, Mr. F. A. Aykroyd, Mr. C. W. Bridgland, Mr. J. W. Buckle, Mr. Harry Dawson, Mr. J. W. Downs, Mr. A. Hitt, Mr. James D. Law, Mr. A. F. Mombert, Mr. George E. Priestman, Ald. Thos. Sowden, Mr. Fredk. W. Turner, and Mr. W. H. Watson; Sir James P. Hinchliffe and Sir Percy Jackson (West Riding County Council), Ald. J. A. Guy (Chairman, Education Committee, Bradford), Mr. Thos. Boyce (Director of Education, Bradford). Mr. Fredk. A. T. Mossmann (Bradford Incorporated Law Society). Mr. F. W. Brearley (Bankers' Institute); Mr. C. A. Laurence (Midland Bank, Bradford); Mr. H. E. Wood (Barclays Bank, Bradford). Mr. Ernest Hickson (President, Society of Dyers and Colourists); Mr. Sydney E. Illingworth (President, Bradford Textile Society); Mr. A. Ollerenshaw (President, Halifax Textile Society); Mr. Wm. Scott (President, Shipley Textile Society). Representatives of the Textile Institute present included—Col. F. R. McConnell (Past President), Mr. Geo. Garnett (Vice-president), Mr. John Crompton (Chairman of Council), Ald. W. Frost (Hon. Secretary), Mr. T. Fletcher Robinson (Hon. Treasurer), Mr. Frank Nasmith (member of Council), Mr. J. D. Athey (General Secretary), Mr. H. L. Robinson (Editor *Journal*), and Mr. F. R. Thurlow (Assistant Secretary, Yorkshire Section).

Lord Emmott, in proposing the toast of "The Textile Institute," coupled with the name of Mr. John Emsley, congratulated the Institute on having obtained its Charter. The Institute would now, he said, be able to grant diplomas to those who practised textile technology, and would be on a par with such organisations as the Institute of Chemistry, the Institute of Mechanical Engineers, the Institute of Civil Engineers, and other similar bodies. In close co-operation with the Universities, a body of certificated technologists would soon arise who would not only provide an adequate supply of teachers but would become leaders of, and advisers to the textile trades. Scientific knowledge and experience were becoming increasingly necessary in the development of industries, and in this country, if he might venture a criticism, there had been too much rule-of-thumb. Too many of the practical Yorkshire and Lancashire manufacturers had almost a contempt for science, simply because they possessed those inherent qualities that made for success even in the absence of science. He was disturbed by the manner in which this country seemed to lag behind in new industries; and he hoped that the efforts of the Institute would at any rate keep us to the forefront in the great textile trades, in which we had been pre-eminent for so long a time. To Mr. Emsley he wished to offer his congratulations on the energy and generosity with which he had worked for the granting of a Royal Charter. Without Mr. Emsley, he doubted whether the Charter would have been in existence to-day; and he also wished to congratulate the Secretary and all others connected with the Institute who had helped in the movement. With regard to the general conditions of industry, he thought there was a rather better outlook. The decrease in unemployment, although there might be special reason that accounted for part of it, had been very marked and gratifying in the last two or three months. There was not so much heard about foreign contracts going to other countries. The stabilisation of exchanges in certain foreign countries, so far as it had gone, had helped rather than hindered us in the great competition that had to be met. Even in the wool trade and the cotton trade, the much lower prices that now existed should stimulate demand very considerably in the future. At the same time, we were more dependent on export trade than any other great country, and our great export trades were depressed on the whole. Until real improvement took place in these trades, there could not be anything like real prosperity in this country. The world was poorer. They were told by Sir Arthur Balfour's Committee that we were still retaining our proportion of the world's decreased export trade, but when he examined in detail some of the trades of this country he did not like what he saw. In the wool trade he did not think there was any reason to be unduly alarmed. If they had been depressed during the past year they could afford it, and it did not seem to be in any way a permanent depression. In the cotton trade there had been four or five years of acute continuous depression in the American branch of the trade, whilst France, Belgium, Holland, and Italy were working full time and making good profits. That was not a satisfactory state of things. Japan, too, was making serious inroads on the markets which we used almost to command. The basic fact was that cotton goods were too dear. The peoples of the tropical countries, receiving only 50 per cent. more for their commodities than they did before the war, could not buy so much cotton cloth as they used to do because it cost $2\frac{1}{4}$ times as much as before the war. In order to ensure full employment we needed to export about 6,000 million sq. yds. of cotton cloth, as against the 4,400 million sq. yds. of last year. He agreed thoroughly with the suggestion of Sir Christopher Needham that a committee should be appointed to investigate the whole position. It should be a committee which could tackle the problem with a perfectly open mind. He would suggest that it should include a prominent financier, a competent statistician, probably from outside the trade; a well-informed merchant; a thoroughly good spinner and a manufacturer; and a satisfactory representative of the operatives. No reasonable employer wanted to reduce wages; but if there was

no way of meeting the question without tackling wages, any reduction that might be made should be with the object of getting back to full time; and if there were any improvement in conditions, there should be effectual guarantees that a large part of that improvement should go to the workers and not to capital.

Mr. John Emsley, in replying to the toast, said that for too long in this country trade had been regarded as secondary to the professions. The textile trade, through the granting of the Charter, had now an allied profession, that of textile technologist, to which he hoped the best brains in the country would be attracted. There were endless possibilities before the textile industry, and all the sciences must be utilised for its needs. Perhaps in this country we had been a little too lax and self-complacent in industry, but we were wakening up and tackling our difficulties from the bottom, and he believed a period of greater prosperity was in store.

Mr. John Crompton (Chairman of the Council) then presented to Mr. Emsley the first Fellowship of the Institute. He said they must recognise the good work done by those who had preceded the Institute in this matter. The City Guilds of London were the pioneers of technical education; and there had followed the textile departments at the various Universities, where diplomas were granted which in themselves were quite sufficient to justify the Institute in awarding fellowships. But the Institute Charter stipulated that those to whom fellowships and associateships were granted should have specific periods of practical experience in the industry, so that they should not only be qualified from an academic point of view, but from the point of view of actual experience of the industry.

Mr. Crompton then read the address embodied in an album which contained the first Certificate of Fellowship of the Institute to which Mr. Emsley had been admitted. This address was as follows—

To JOHN EMSLEY Esq., J.P., Bradford,

President of the Textile Institute (Incorporated by Royal Charter 1925).

Desiring to place on permanent record their deep sense of appreciation of your services to The Textile Institute during the period of your Presidency (1922-3 to 1925-6), the Council of the Institute hereby present to you, on behalf of the Officers and Members generally, this Address of Congratulation upon the successful issue of your efforts to secure a Royal Charter of Incorporation for the institution.

Since the inauguration of the original Institute, incorporated under the Companies (Consolidation) Act in 1910, several proposals have been considered with a view to the creation of Diplomas on a basis of recognised qualification in Textile Technology in connection with Institute Membership. For various reasons, however, postponement was necessary.

After election as President in 1922, your immediate recognition of the importance of conferring Diplomas upon qualified members prompted you to assist a movement with this object in view. By your assistance and generosity, hereby gratefully acknowledged, all obstacles were removed, and the Institute was enabled to proceed with the presentation of a Petition to His Majesty's Privy Council in favour of the grant of a Royal Charter of Incorporation.

The preparation of the Petition, the framing of the Charter and Bye-laws, and the negotiations generally, occupied a considerable period of time, and your determination to witness the completion of the task you undertook in 1922, demanded repeated extension of your presidential services which you willingly undertook.

In the fourth consecutive year of your Presidency the grant of the Royal Charter was received.

Proceedings in celebration of the grant of the Charter have taken place at Manchester (14th October 1925), London (23rd October 1925), and Bradford (25th January 1926). It is in connection with the last-mentioned fixture that the

Officers and Council of the Institute ask your acceptance of this Address of Congratulation upon the success of the movement to obtain the Charter. This request is made in the firm belief and conviction that your efforts and generosity will prove of enduring benefit to the Institution and to the Industry which it seeks to serve.

The Selection Committee (Diplomas) of the Institute, appointed under the terms of the Royal Charter and Bye-laws of the reorganised chartered Institute, of which Committee Mr. J. H. Lester, M.Sc., is the first Chairman, has unanimously recommended that the first Diploma to be awarded by the Institute shall be to yourself, as President, and the Council of the Institute unanimously approved of the recommendation. Herewith, therefore, is also presented to you the First Certificate of election as a Fellow of the Textile Institute.

The Council desires to record its deep sense of admiration of your untiring zeal and practical help not only to the Institute but to many causes with which your name and service are prominently identified—causes calculated to promote the advancement of the textile industry and the general well-being of all concerned therewith.

(*Signed*) John Crompton, *Chairman of Council.*
Wm. Frost, *Honorary Secretary.*
T. Fletcher Robinson, *Honorary Treasurer.*
J. D. Athey, *General Secretary.*

The presentation of the Fellowship was then made amidst applause.

Mr. Emsley, in replying, expressed his appreciation of the grant of the Fellowship, which, he said, he would treasure to the end of his days, and would also be an inspiration to his grandson. He hoped that eventually the Institute would see to it that its Fellowships were endowed in order that those who were suitable and were not engaged in the industry itself could continue their studies.

Mr. George Garnett (Vice-president), in proposing the toast of "Our Guests," said the textile industry was out for a higher status, and their guests could help them in achieving that object, representing as they did, Parliament, the municipalities, the education authorities, various branches of industry, banking, and the law. He thought there was a brighter prospect before the industry because it would be based in future on a wider knowledge and a greater spirit of co-operation.

The toast was responded to by the Lord Mayor of Bradford (Ald. J. Stringer), Sir James P. Hinchliffe (Chairman, West Riding County Council), Mr. H. Sutcliffe Smith (Chairman, Colour Users' Association), and Lieut.-Col. A. Gadie, M.P. for Central Bradford.

Mr. H. Sutcliffe Smith mentioned as an instance of the enterprise of the wool textile trade that in three or four branches of the Bradford Dyers' Association no less than 50,000 patterns had been dealt with during last year. That showed that Bradford was on the look-out for new things to tempt the buyer. He paid tribute to Mr. Emsley's efforts not only in connection with the Charter but also in the movement to bring the wool textile industry into closer touch with the retailer. A further step in that direction was to be taken the following day, when they were going to meet the wholesalers. There had been bitter complaints that more sympathy was shown to French sellers than British sellers, and they hoped at that meeting to remove misconceptions and create an atmosphere in which British goods would be better received.

Lieut.-Col. A. Gadie mentioned that in December 20,500,000 gallons of water were consumed in Bradford, against 17,800,000 gallons 12 months previously, and attributed the increase to trade requirements.

The gathering concluded with a vote of thanks to Mr. Emsley for presiding, proposed by Mr. John Robinson.

London Section

Meeting at the Clothworkers' Hall, Mincing Lane, London, 15th November 1925. Chairman, Mr. C. B. Gwynn.

THE FINISHING OF COSTUME CLOTHS

Opening the proceedings, the Chairman said that he had himself, for the past twenty years, represented the interests of a great dyeing association which would be well known to many of those present. Unhappily the dyer and finisher was the man to whom the cloth went last, and the consequence was that if there was a fault in a piece of cloth, it was always put down to the poor dyer. He contended that to make a piece of cloth absolutely perfect in every respect would be a wonderful thing—a piece of cloth perfect in every respect from the point of view of weaver, dyer, and finisher. He hoped that after they had heard the lecturer they would be a little more sympathetic towards the dyer. If any of those present were in Yorkshire at any time he extended to them a very hearty invitation on behalf of his Association to go over their dye-plants, and he thought they would come away with a different impression.

Capt. H. Jennison, M.C., the lecturer, then said—To-night I propose to deal with the finishing of light weight dress goods, but at the very outset may I point out that the term "finishing" is very broad in its application, and it is my intention to start at the very beginning, leading to the finishing processes later, since, paradoxical as it may seem, the best finishes can only be obtained by the greatest care being taken in the preliminary treatment. The following short résumé may indicate how the ultimate results can be affected before the cloth reaches the dyer or finisher. At the very commencement, the sorting of the wool has a bearing on the ultimate handle of the cloth, since, as all of us know, botany wool gives a much softer handle than cross-bred. Combing also has its effect, the longer hairs giving us worsted cloths, and the shorter hairs woollens. In spinning, the degree and the amount of twist is of great importance in the production of cloths; any variation in twist may result in streakiness or weft bars. The choice of a suitable non-drying oil for use during combing and spinning is also of the greatest importance to the dyer, since a dried or semi-dried oil can only be removed with the greatest difficulty, giving rise again to "barriness," or streakiness. During weaving, mechanical faults are liable to occur which, if not corrected before the piece is dyed and finished, may give rise to faults then too late to remedy. The pieces must therefore be examined carefully at the weaving shed, and any faults discovered mended by girls. The pieces will now be ready for handing to the dyer, but before we go any further, it would be as well to give you a rough idea of the organisation of the dyeing and finishing industry in general.

Speaking broadly, the industry may be divided into three groups. First, there are a few self-contained firms who buy wool in the raw state, from which they manufacture cloth, and afterwards dye and finish it. Secondly, there are a large number of firms who dye and finish goods on commission—this means that the cloth to be treated never really belongs to these commission dyers and finishers, but simply passes through their hands, afterwards being returned to the customer or being delivered elsewhere at his instruction. Lastly, there are several small firms who dye cloth on this same commission basis, afterwards handing it on to other firms to be finished. The majority, however, may be grouped in the second class, which dyes and finishes cloth on a commission basis, and it is from this point of view that we shall deal with the cloth.

One of the first steps generally taken when new cloths have been designed is for pattern lengths to be made, which can be treated before any pieces are manufactured, in order both to note the finished result and to check the designer's calculations of shrinkage for costing purposes, after which the cloths are shown

as travellers' samples, from which you gentlemen buy your season's goods. Orders, may we hope ! are now placed and goods are put into work, and after weaving and burling and mending, they are in most cases sent to the dyer to be held in his greyroom until instructions for colouring up have been received. This may entail the storage of as many as twenty thousand pieces in the dyers' greyroom. Naturally, as these pieces do not belong to the dyer, every precaution must be taken to preserve them from damage or loss, the chief danger of course being from fire, and this means that very heavy insurance premiums have to be faced.

The lecturer then proceeded, by the use of slides, to describe the various processes employed in dyeing and finishing; he mentioned first the process known as "crabbing" to which botany cloths are generally subjected in, which consists in essential of winding the cloth under tension through troughs of boiling water on to rollers. Cross-bred cloths require the further treatment of "steaming" which process involves the use of a perforated iron cylinder upon which the fabric is wound. Steam is then blown through the cylinder and outwards through the piece. The better class fabrics are then put through a "scouring" process, to remove the 3 to 4% grease or oil they contain. Pieces destined for light or pastel shades require the utmost care, and it has to be said that manufacturers, as a whole, take every precaution against dirtying such goods. Samples were produced by Captain Jennison to illustrate the difference between the grey cloth and the prepared and scoured article, and he pointed out how much closer in texture the cloth had become, thus giving a fuller and softer handle. The "milling" process employed in the production of such cloths as cheviots, estamines, velours, vicunas, &c., was next described, and samples shown of cloths which had been milled and "stock" milled. After scouring or milling, the pieces contain from 100% to 150% of water, which renders them difficult to handle. As a rule a large proportion of this water is removed by a hydro-extractor, which process was described by the lecturer. The case of goods coloured from the grey, either with acid wool colours or, for faster colours, by chrome-fixed colours, constituted the next part of the lecture, and the function of a mordant was described at this point. The method followed in indigo dyeing was then outlined, and it was pointed out that while in the vat no part of the cloth was allowed to come above the surface of the dyestuff, as any part so exposed became darker in colour than the bulk. A slide of a typical indigo vat was displayed and its variation from an ordinary dye-vessel pointed out. To prevent "rubbing," the pieces are treated in a scouring machine with Fuller's earth.

Assuming that the dyeing process is completed, the dress goods would now be ready for drying, but in the case of suitings and such cloths as venetians it is often necessary to treat the pieces further in order to obtain the finish required. After dyeing, or any subsequent treatment, the cloth is again hydro-extracted to remove all surplus moisture, after which it is ready for drying. There are two alternative methods of drying the cloth, the first being to run it over a series of steam-heated cylinders, and the second to dry it in a heated chamber, the cloth being held at the selvages by means of pins, which can be adjusted for width. The latter method is generally employed for better quality cloths, since it imparts a much nicer handle and has the advantage that it is possible to control the width at which the pieces require to be dried. The treatment given to the pieces so far cannot be regarded as very gentle, and it is hardly to be expected that even the best of cloths should emerge from the drying machine without being slightly ruffled, so much so, that in practice it is found necessary to clear the face of the cloth by cutting or cropping. A cropping machine consists of a circular rotating blade very similar to that used in a lawn mower, except that more blades are employed and that it requires to be set with a very much finer degree of accuracy, in fact, in actual practice, a cropping blade will shear a sheet of the thinnest tissue paper procurable. The cloth, held under tension, passes over a frame called the bed, and the blade is adjusted to the

cloth so that all the rough hairs are cut away, leaving a very much improved material. This bed is hollow, so that if any small defects are present the cloth will have space to sink slightly below the level of the knife edge, and in this way avoid the danger of cutting a hole into the piece. Other machines are fitted with a solid bed, which allows much closer setting of the blade to the cloth, but raises the danger of small holes being cut wherever a knot occurs, since with a bed of this type the cloth cannot sink and the blade cuts through the knot; these machines may have as many as four blades. The pieces are then examined for evenness of dyeing, shade matching, and general satisfactoriness. They then pass on to the burlers and menders. Discussing this part of the industry, Captain Jennison emphasised the enormous increase in the employment of burlers and menders, and instanced figures of one concern in which these wages had risen 492% since 1904, and of another firm which in 1910 paid £3,792 for this work and in 1923 £12,725.

The lecturer proceeded to describe the "finishing" of such fabrics as serges, gabardines, poplins, &c., pointing out that "finishes" for other cloths were only modifications of the process he proposed to describe. In the dry-blowing or decatising process, the cloth, open width, is wound on to perforated cylinders between layers of heavy weight cotton wrapper. Steam is then blown through the cloth, giving it a firm handle, and at the same time removing all creases which may have developed during the perching and burling. The pieces are then stamped on the selvage according to the finish being given. This is becoming the general custom, the main feature being the security given to the customer, since no dyer or finisher can afford to fix a stamp on his cloth unless he is confident that it will give satisfaction. After stamping, the cloth is rigged, which means that it is doubled along its length, one list being superimposed on the other, after which it is ready for pressing. In carrying out this treatment the cloth is folded between sheets of specially prepared cardboard, so that they are in contact with both back and face of the material. They are then placed in a press consisting of a base, below which is an hydraulic ram. Each press will hold from 14 to 16 pieces, one above the other. Heat is necessary in order to obtain the result required, and papers are warmed by means of steam-heated metal plates before they are inserted into the pieces. Pressure is now applied, and after the pieces have remained a few hours, with a pressure of from one ton to twenty-five hundredweights per square inch on the hydraulic ram, they are taken out and "turned," which means that the papers are taken out and replaced in such a position that the previous fold of the cloth is situated in the centre of the press-paper. If this were not done, a dark mark would be visible across the piece where no pressure had been applied. The pieces are then reinserted in the press and a pressure of two tons per square inch of ram surface is applied for a further period, by which time the papers will have gone cold and the cloth will be well set. If the cloth could now be examined it would be found to be glazed both on the back and the face, and in this condition would be quite unsuitable for sending into the market. It is therefore necessary to give the face a dull appearance, which is produced by passing the cloth, face downwards, over a box containing live steam, until a perfectly level dull finish is obtained. This may entail as many as four passages over the steam box, in order to obtain the desired effect, gentle steaming being essential in order not to affect the back of the cloth too much, and it must be left with a small amount of press on in order to give a nice handle. The goods are then left under their own weight with a layer of metal plates on top of the pile of pieces.

The pieces are now ready for delivery, unless a still better finish is required, which is produced by "London shrinking." To produce this finish, the cloth is led at open width between wet blankets which wet the cloth, and remains between these blankets until a heating action takes place, and the cloth begins to steam of its own accord. This treatment leaves the cloth in such a condition that, when hung up to dry, naturally, without any tension either on the width

or the length, all the stretch produced in the various processes is eliminated, and the cloth is in its natural state, thus ensuring that in the subsequent making up no shrinkage can take place, and the cloth will keep its shape. The pieces are now re-pressed, steamed, and laid as before, severity of the treatment of course being reduced considerably, after which they are again ready for the market.

This method of finishing, with slight variations, may be regarded as the standard for all classes of gabardines, serges, poplins, and variants such as covert cloths, panamas, &c. When we come to velour cloths, estamines, and faced cloths, we must return to the stage at which the cloth left the dyeing machine. The cloth will have been milled before dyeing in order to give it solidity, and it is now raised to produce the cover associated with this class of material. This is done by brushing the cloth with wire brushes which raise the fibres from the ground, giving the pile effect. A portion of this pile is then cut away on a cropping machine, after which the cloth is again run over the raising machine, in this way thickening the pile. This cycle of operation is repeated until the desired result is obtained, after which the cloth may be pressed lightly in order to give it a smooth handle. These, then, are the main operations generally employed for dyeing and finishing cloth, different results being obtained by slight variations in the various processes.

The Hon. Secretary of the Section, Mr. A. R. Down, thanked the lecturer for an extremely interesting paper. He regretted the absence of Mr. Edwin Wigglesworth, who had another engagement of long standing. He personally would not fail to take advantage of Mr. Gwynn's kind offer when next he was in Yorkshire. He had always thought that dyers were a somewhat secretive folk and was glad to find that this was not so in the case of the Association with which Mr. Gwynn was connected.

The vote of thanks was seconded by Mr. P. J. Neate and, after a brief reply from Captain Jennison, the proceedings terminated.

Irish Section

Meeting at the Municipal College of Technology, Belfast, 5th February 1926, *Mr. F. Anderson in the chair.*

THE USES OF ARTIFICIAL SILK IN THE PRODUCTION OF TEXTILE FABRICS

Though Textile Institute meetings at Belfast do not take place with great frequency, yet the meetings organised there are usually associated with a highly satisfactory measure of support and enthusiasm. On the evening of the 5th February, Mr. A. B. Shearer, F.T.I., of Manchester (Official Lecturer for Messrs. Courtaulds, Ltd.), contributed a lecture on "The Uses of Artificial Silk in the Production of Textile Fabrics." In connection with the lecture an exhibition of fabrics and yarns, by the firm named, took place on the 3rd, 4th, and 5th February. The events took place at the Municipal College of Technology, excellent facilities having been generously granted by the Technical Instruction Sub-committee of that institution. The Principal of the College (Professor J. Earls) took an active interest in the fixture, whilst Professor F. Bradbury, of the Textile Department, assisted in every possible way. The exhibition was attended by large numbers of representatives of the textile industry in Northern Ireland and considerable interest was taken in the proceedings.

The lecture by Mr. Shearer took place on the Friday evening in one of the lecture halls of the College, when the attendance was even larger than had been anticipated.

Mr. Frank Anderson (Portadown) presided, and alluded to the progress of

common meeting ground for the various branches of the textile industry for the consideration and discussion of technical and scientific problems relating to the various fibres and their products. The need for the Institute had been amply demonstrated. The present meeting was the first held at Belfast since the Institute obtained its Royal Charter, and he was pleased to be able to state that of the diplomas which the Institute had already granted to members, under the terms and powers of the Charter and Bye-laws, one or two had already been secured by members in the Belfast district. With regard to the subject of the lecture, the developments in artificial silk had certainly been phenomenal and had introduced a new factor affecting the demand for yarns and fabrics. The artificial filament was assisting greatly developments in composite fabrics, particularly in the cotton and woollen trade. In the linen industry there had not been so much replacement or substitution, but demands which had arisen were being met. An important problem, perhaps, was that of keeping pace with the developments in yarn and fabrics with the retention of their particular plant.

Mr. A. B. Shearer, in the course of his lecture, after referring to the introduction of the artificial filament, said there was usually some good and sound reason for any innovation which took place in regard to the raw material of an industry. Fashion and the demand for increasing variety of ornamentation in fabrics were doubtless responsible for the production of what was to-day known as artificial silk. Fashion had brought about a marked diminution in the quantity of material required, and this diminution had brought about a searching for extended variety. Lustre was an important consideration in the securing of decorative effects, and as silk was somewhat prohibitive in its price, the new material was forthcoming to meet the demand. The artificial silk industry had grown in the lifetime of most people present, and its growth had really been enormous. Great Britain was the second largest consuming country in the world and advanced from two million pounds weight in 1913 to about four million in 1919. In 1924, the consumption was about 28 million pounds, and last year it must have been at least 35 million pounds. The world's production had proceeded apace. In 1922, it was about 80 million pounds, 1923 97 million, 1924 140 million, and in 1925 180 million pounds. So far, the amount was very small when considered as a textile fibre. Nevertheless, real silk was an important textile industry, and in 1924 the world production of natural silk was only 86 million pounds. Therefore, in 1924 the production of artificial silk was nearly twice that of the real. To-day, he considered it was reasonable to regard artificial silk as the third most important raw material for the textile industries, and it had jumped into this position in a very few years. He saw no reason why, eventually, artificial silk should not be produced which would be as strong as silk and be the strongest fibre available.

It was not difficult to deal with from the manufacturers' point of view, given a thorough understanding of its properties and the properties of the other fibres which were used with it. Greater scope had been given to designers by its possibilities in regard to new textures, and some highly interesting materials were now being produced, more particularly in Yorkshire, from mixture yarns. Great care should be taken that surfaces with which artificial silk had to come into contact during manufacture should be cleared of rust and inequalities. Even slight friction was detrimental, and, inasmuch as lustre was one of its outstanding features, it followed that the minimum of handling should be aimed at.

Discussion

The Chairman said the wide difference in behaviour of artificial silk, as compared with flax, presented considerable difficulty, and, in combining artificial silk with linen, the difficulty intensified in progress of manufacture. They were indebted to Mr. Shearer for his address, not only on that occasion, but for

the useful discussions he had engaged in earlier in the day with visitors to the exhibition.

Replying to questions, Mr. Shearer said he preferred to retain an open mind as to combination of artificial silk and flax. Flax, in certain respects, was almost too much akin to artificial silk, and this had the effect of the two yarns slipping on each other. Wool was entirely different; it gripped anything in contact with it, whilst it felted easily. Careful tensioning was absolutely necessary. Viscose behaved very differently from flax, and the stretch and regain of the yarn as it went through had to be fully considered. This consideration was important because the introduction of artificial silk was leading to keener appreciation of the properties of the fibres with which the industry was already accustomed. It was to be remembered, too, that what might at first be regarded as a fault might be turned to good account so as to yield an effect which the designer desired, and the fault might be turned into a virtue.

Asked if operatives experienced difficulty in dealing with artificial silk, he said that greater care generally meant greater cleanliness. Generally speaking, its manipulation was attractive to the operative.

Replying to a question as to occurrence of "bright picks," he said the whole matter boiled down to consideration of tensioning. Properly spun viscose should be level and have level dyeing qualities. In combining artificial silk with linen, the linen should be as near to bleached as possible before combination. Dry atmospheric conditions were desirable, for the greater the humidity the less was the working strength of the viscose. Regarding a question as to sizing or dressing, the lecturer said it was obvious that ordinary size (starch), which had no lustre, should not be used. Ready sized warps were now available.

Mr. J. D. Athey, General Secretary of the Institute, moved a vote of thanks to the Lecturer, to the Chairman, and to Mr. Yates (Messrs. Courtaulds, Ltd.) for their services, and in doing so referred in some detail to the aims of the Institute and the conditions governing the grant of diplomas.

Professor F. Bradbury seconded, and said there had been abundant testimony to the fact that the three days' effort on the part of the Institute at Belfast had been thoroughly worth while.

The vote was heartily accorded.

YARNS FOR THE HOSIERY TRADE

Conjointly with the British Association of Managers of Textile Works, a meeting was held at the Institute, Manchester, on Saturday, 23rd January, when Messrs. J. Chamberlain (Technical School) and J. T. Stokes (Secretary of the Textile Society), both of Leicester, gave a lecture on the above subject. Mr. Chamberlain dealt with the properties desirable in yarns for the hosiery trade. The ideal yarn, he said, would possess uniformity, good covering power, plasticity, elasticity, cleanliness, lustre, and good dyeing and bleaching properties. In addition, it should possess high tensile strength, and should be unshrinkable. He then dealt with the classes of yarns used as determined by the fibres from which they are made, and passed on to describe the part played by machines in relation to the choice of yarns to be employed in knitting processes. His next and last topic was the marketing of yarns.

Mr. Stokes, in a very practical and direct way, put before all present his views as to the possibilities of Lancashire developing a trade with Leicestershire in hosiery yarns. Extended credit demands, difficulty of securing the exact class of yarn required, and special demands as to winding, he mentioned as obstacles. To any spinner desiring to go in for hosiery yarns, he urged regularity in counts, extra care in regard to cleaning and carding, and delivery on cones.

It was stated at the meeting that it was hoped to continue the discussion at a meeting at the Textile Institute on Saturday, 20th March, the last day of a three days' exhibition of knitted fabrics and yarns.

NOTES AND NOTICES

The Council of the Institute

At the February meeting of the Council (17th inst.) at Manchester, an unusually lengthy agenda was submitted and the business was disposed of with comparatively marked dispatch. Mr. John Crompton (Chairman) presided, and there was not a large attendance, the tendency towards small meetings, as a result of the experiment of holding meetings monthly in place of quarterly, persisting. It was an obvious advantage that the Finance Committee now having been resuscitated had paved the way to facilitating the conduct of the business. An important item was the recommendation of the Finance Committee for certain rearrangements in regard to the staffing of the London offices of the Institute, and the Council readily acquiesced in the proposal that Mr. William Frost (Chairman of the Finance Committee) should confer with the London Section Committee and present definite proposals on the subject. A recommendation from the London Section Committee that a contribution should be made to the funds needed in connection with the special Inquiry into Relationship of Technical Education to other forms of Education and to Industry, of which the Rt. Hon. Lord Emmott, G.C.M.G., is Chairman, was considerately received, and it was agreed that the Institute should contribute ten guineas. It was reported to the Council that the Cotton Textile Industry Committee (British Empire Exhibition 1924) had remitted to the Institute, per the Hon. Secretary, Mr. Frank Nasmith, a cheque value £83 4s. 7d., being surplus of the funds of the Cotton Textile exhibit which the Committee had had pleasure in voting as a donation to the Foundation Fund of the Institute. This acceptable gift was gratefully received and the Secretary to make suitable acknowledgment on behalf of the Council. The fact may be stated that in some measure at any rate the gift represents acknowledgment of the facilities granted to the Committee in question for the holding of their meetings at Manchester. The Council decided that the Hon. Treasurer, Mr. T. Fletcher Robinson, should proceed with investment of the £100 odd now standing at the bank to the credit of the Foundation Fund. One other item may be mentioned—that the Council received with the greatest regret the intimation of Dr. W. Lawrence Balls that in consequence of removal from the Manchester district he proposed to resign membership of the Council and Committees of which he has been long a member, and it was decided that Dr. Balls should receive the warm thanks of the Council for his past services. The matter of the next Annual Conference at Buxton was also mentioned at the meeting, and the Council were gratified to learn that Sir William H. Bragg, K.B.E., F.R.S., had kindly consented to contribute the annual Mather Lecture on Thursday, 27th May, at the Conference at Buxton.

Forthcoming Election of Council

In response to the issue of nomination forms in respect of the forthcoming election in connection with the Council of the Institute, the General Secretary reported to the Council that sufficient nominations were now to hand to make it quite certain that a contested election will take place. Thirteen nominations had been received from individual members and, including nominations by the Council, the number is brought to sixteen for the ten vacancies. Nomination forms have been sent out to all members, but members are asked to note that the final date for receipt of nominations is 16th March. All nominations for Vice-Presidents and Ordinary Members of Council should be made on the special forms provided, and additional nomination forms will be forwarded to members on request. Every nomination form must relate to one vacant place only and must be signed by two members of the Institute and also by the nominee, who must also be a member of the Textile Institute. It is important to note that in addition to individually secured nominations, the Council itself is empowered

to nominate. In due course voting papers will be issued containing the names of the candidates and distinguishing those nominated by the Council. These will be sent out at least 14 days prior to the date of the Annual General Meeting, 21st April, all voting papers having to be returned to the General Secretary at least four days prior to the said meeting.

The Publications Committee

Items of general interest to members arise from time to time in the deliberations of the Council and of Committees of the Institute, and it is one of the functions of these "Notes and Notices" to place on record such matters. At the February meeting of the Publications Committee, it was decided to institute a feature for the Proceedings Section of this *Journal* by which obituary notices would be published. The first such notice appears in this issue—Professor William Myers. In this way, it is hoped to place on record tributes to the memory of any prominent member of this Institute who may have passed away. Under the heading "Section Activities," the January issue contained a reference to a new development which owes its inception to the Publications Committee. The reading of papers, ultimately to appear in the Transactions Section of the *Journal*, at Institute meetings, would, it was thought, afford technical and scientific interests an opportunity to discuss common problems from their respective points of view. This may be said to have characterised the meeting held on 12th February at the Institute, though on this occasion no doubt the discussion became rather too scientific in terminology for close following by all; none the less the requirements of the practical side of the industry were kept well in sight throughout. For this, credit must be accorded to the Chairman of the meeting, Mr. Percy Bean, whose plea throughout was for the view-point of the spinner or weaver never to be lost sight of. But, from the discussion, two main points emerged—first, that scientific workers should agree upon working definitions, and, secondly, that the practical man should express as clearly as possible exactly what qualities or properties he desires in his yarns or materials. That these points have been made before more than once is well known, but the meeting under review brought out two practical and specific examples. The first was that generally-accepted and understood definitions of "elasticity," "pliability," and "plasticity" should be sought, and, secondly, that careful investigation should be made into the real desiderata for yarns to be used in weaving both generally and specifically from the point of view of the cloth under construction. Are yarns to be strong from the point of view of their direct breaking strength, or to be elastic, or to be pliable? Not that one of these qualities is to be sought to the exclusion of the others, but that one may be preferable to the others in the light of the behaviour of yarn in the loom. Having settled that point, if it can be settled yet, it would probably be desirable to set about securing some simple method of measuring elasticity or pliability, comprehensive alike to the shed manager and to the technical director. Possibly, even probably, many engaged in the industry consider that these points are already settled—that they have a means of judging or measuring the qualities desired. The discussion on 12th February showed very plainly that such knowledge was not universal. Only by joint discussion of these similar problems by those really concerned can satisfactory terms of definition be arrived at, and adequate means of measurement and expression of measurement be secured. It is hoped that such discussions may soon be arranged in addition to the reading of further papers of a technical and scientific character.

Linen Industry Research Association

It is announced that Dr. J. Vargas Eyre is relinquishing the Directorship of the above-named Association, which has its Research Institute at Lambeg, Co. Antrim. At the end of March, Dr. Eyre is to take up similar duties for the Distillers Co. Ltd., with a view to the development of a central research

institute and the building up of a new research organisation for the interests indicated—in fact, to carry out a somewhat similar scheme to that which has been carried forward in connection with the linen trade. In consequence of the appointment, the Directorship of the Linen Industry Research Association will be vacant after 31st March. Dr. Eyre states that he has found it extremely difficult to decide upon the change in question, the more so on account of the extremely cordial relations which he has experienced with all concerned with the Linen Research Association, and also in view of the splendid support which his staff has extended to him on all occasions. It may be here stated that Dr. Eyre's association with this institute, and particularly his services on the Publications Committee, for several years past have been greatly esteemed, and officers and members of the Institute, whilst regretting his transference to another industry, will wish him every success in his new sphere of activities.

Technical Education and Industry

At the beginning of 1925 and as the outcome of a general meeting of interested persons, a Committee was formed in London under the chairmanship of Lord Emmott, and with Mr. J. Wickham Murray as Secretary, to inquire into the Relationship of Technical Education to other forms of Education and to Industry. The Textile Institute was invited to nominate two representatives for this Committee, and, accordingly, Messrs. E. B. Fry and A. E. Garrett, members of the London Section Committee, were appointed delegates. At a meeting of this Committee on the 18th December 1925, it was reported that the Secretary for the Board of Education had clearly indicated his sympathy with the Inquiry, and also that certain arrangements were being made to prevent overlapping between this Committee and H.M. Government's Committee on Education and Industry. It was agreed to pursue the Inquiry by means of questionnaires, a special questionnaire to be prepared to which Universities should be invited to reply. Mr. E. B. Fry, reporting to the London Section Committee of the Textile Institute on the work done by this Committee, states that "this Inquiry is now getting into good shape, and a special Executive Committee of six has been appointed to draft finally the questionnaire which is to be sent out to all the Technical Schools and Colleges, the Universities, Education Authorities, and representative firms selected from various classes of industry. Answers to the questions will be collated and reported upon to the General Committee for further consideration and action." The wide scope of the Inquiry, and its obvious importance to the vital question of technical education, render its proceedings a matter of serious interest, and a report of later work and conclusions drawn from the questionnaire should prove of great value to the textile industry.

London Offices of the Institute

The Institute's premises in London, which have proved convenient in many ways to members visiting London, and which serve as offices for the London Section, have for the last nine months also given accommodation to the Association of Special Libraries and Information Bureaux, an arrangement which has modified the Institute's annual expenditure on its London premises. More recently, an additional "paying guest" has been welcomed at 38 Bloomsbury Square, the British Institute of Industrial Art having come to terms with the Council for part use of the rooms. This organisation aims at effecting a closer co-operation between Art and Industry, and has held exhibitions from time to time at important industrial centres with this object in view. It works in close co-operation with the Board of Education and the Board of Trade, and has a consultative panel of some two hundred Fellows, elected for their services to art in its industrial application. The Textile Institute has supported the British Institute of Industrial Art from its inception, and the present arrangement for sharing premises is agreeable to both organisations.

Isidore Spielmann Memorial

The Governors of the British Institute of Industrial Art have decided to apply the legacy of £50 bequeathed by the late Sir Isidore Spielmann (who was a Governor of the Institute from its foundation until his death last year) to form the nucleus of a Memorial Fund to be called after his name. This fund will be used for the occasional purchase of works of modern British Industrial Art considered worthy of a place in the Permanent Collection of the Institute which is now exhibited in the North Court of the Victoria and Albert Museum. All who sympathise with the above object and who desire in this way to express their appreciation of Sir Isidore Spielmann's great services to British Art and Industry are invited to contribute to the Isidore Spielmann Memorial Fund. Communications should be addressed to the Hon. Treasurer, 38 Bloomsbury Square, W.C.1.

Institute Membership

At the January meeting of the Council of the Institute, the following applicants for membership were elected—Phineas Bentley (Mill Manager), Pleasley Works, Mansfield, Notts.; Charles Bownas (Textile Designer), 22 Harrogate Avenue, Sedgley Park, Manchester; Harold Brookes (Textile Designer), 139 Manchester Road, Walkden; C. K. Buckley (Principal), Government Textile School, Cawnpore, India; H. O. Croasdale (Cotton Student), Gayford House, Colne; Gerald Dod (Engineer), 35 Little Peter Street, Manchester; James Duckworth (Assistant, Weaving Department, British Celanese, Ltd., Spondon), 18 Merchant Avenue, Spondon, near Derby; C. B. Gwynn (Director, Bradford Dyers' Association), 128–129 Cheapside, London, E.C.2; W. J. Hall (Research Physicist), 23 Middleton Road, Ilkley, Yorks.; L. Meunier (Professor of Chemistry), 67 Rue Pasteur, Lyon, France; Gerald Park (Assistant Preparation Department Manager, Cotton Weaving Mills), 450 Blackburn Road, Darwen; Srinibas Shaha (First Assistant), Government Textile School, Cawnpore, India; L. B. Sutcliffe (Textile Analyst), Prospect House, Park View Road, Bradford; E. G. Taylor (Cotton Student), 96 Park Drive, Colne; C. A. Thirumudiswamy (Weaving Master, Sitaram Spinning and Weaving Mills, Ltd.), Trichur (Cochin State), South India; C. W. Woodman-Cooper (Silk Salesman), Elmcroft, Pinner Road, Harrow-on-the-Hill; S. V. Naik (Student), c/o Thos. Cook & Sons, London, E.C.4; Samuel Catterall (Carding and Spinning Manager), Elgin Mills, Cawnpore, India; Frank Hopkinson (Director, Bradford Dyers' Association), 41 Leylands Lane, Heaton, Bradford (Yorks.); Fred Kenyon (Overlooker), 97 Chapel Street, Leigh; C. T. Nicholson (Cotton Piece Goods Salesman), c/o Broome & Foster, Ltd., Manchester; H. Duncan Robertson (Weaving Master), Binnyston Gardens, Bangalore City, South India; Arthur Saville (Manager, Francis Willey & Co.), Duke Street, Bradford, Yorks.; George Shackleton (Weaving Manager), 22 Broomfield Street, Queensbury, Bradford, Yorks.; Wm. Smethurst (Textile Designer), 23 Shaw Street, Bolton; John Tomlinson (Dyeing Expert), China Dyeing Works, Jessfield, Shanghai, China.

At the February meeting of the Council of the Institute, the following applicants for membership were elected—George Baxendale (Operative Cotton Spinner; Representative for Leigh Technical Union), 183 Hope Street, Leigh; David Robert Christie (Lecturer on Textile Technology), Scottish Woollen Technical College, Galashiels; Richard H. H. Dawson (Salesman, Textiles), 36 Park Hall Road, East Finchley, London, N.2; Fred Greenwood (Mill Manager and Teacher of Textiles), 107 Tweedale Street, Rochdale; Ernest V. Haigh (Engineer and Cotton Mill Manager), c/o Messrs. John Hetherington & Son, Ltd., Pollard Street, Manchester; Robert A. Hill (Chemist, Silver Springs Bleaching and Dyeing Co., Congleton), 2 Malvern Villas, Hightown, Congleton, Cheshire; Herbert Holroyd (Representative for the Huddersfield Textile Society), Longroyd Bridge Mills, Huddersfield; A. S. Mombert (Managing Director, c/o A. & S.

Henry & Co. Ltd., Bradford), Tablehurst, Park Drive, Heaton, Bradford, Yorks.; Gilbert H. Orton (Textile Buyer), 32 Woodlands Road, Crumpsall, Manchester; F. W. Peerless (Clothworker), 61 Old Street, London, E.C.1; Frederick T. Peirce (Textile Research, Shirley Institute), 63 Kingston Road, Didsbury, Manchester; W. P. Richmond (Mill Managers' Assistant), 21 Bentley Street, Nelson; Fred Scholefield (Dyeworks Manager and Chemist), c/o Burgess, Ledward & Co. Ltd., Walkden, Manchester; George Scott (Hosiery Manufacturer), Messrs. Peter Scott & Co. Ltd., Hosiery Manufacturers, Hawick, Scotland; Walter M. Scott (Textile Chemist), c/o Cheney Brothers, South Manchester, Conn., U.S.A.; Harold D. W. Smith (Textile Chemist and Technician), 75 West Thirty-third Street, Bayonne, N.J., U.S.A.; John Smith (Pattern-room Foreman, and Textile Teacher, Bolton Evening Classes), 22 Old Clough Lane, Walkden, near Manchester; J. Woodhead (Mill Manager), Firth Mill, Skipton, Yorks.; H. J. S. Dewes (Manufacturer of Specialities of Oils and Fats for the Textile Trade), Heathfield, Cross Lane, Latchford, Warrington; Norman Jepson (Sales Manager, Cotton Spinners & Manufacturers), Talbot Villas, Talbot Street, Glossop; G. H. Thompson (Mill Manager and Director, Cotton Spinning & Doubling), 146 Coppice Street, Oldham; J. McKay Adan (Textile Designer and Representative), 52 Bedford Place, Aberdeen, Scotland; Donald Wilson (Textile Lecturer, Preparing, Combing, and Spinning; and Worsted Spinners' Order Clerk), 15 Harker Terrace, Stanningley, near Leeds.

OBITUARY

Prof. William Myers

By the sudden death of William Myers, Professor of Textiles in the College of Technology and the University of Manchester, technical education in this country has lost one of its most striking personalities. Though he had specialised in the processes of weaving and allied subjects, his knowledge extended over the whole field of textile technology. His place in the hearts and minds of those who knew him does not rest upon his knowledge and his teaching but upon the broader and more enduring foundation of his humanity. From the moment a student presented his admission card to the time when he left the College to enter the textile industry, William Myers was his friend. William Myers was loyal not only to those under his charge but also to those officially above him. The very word loyalty was indeed almost a watchword with him, and to him disloyalty was a crime. Through all the changing adjustments which progress demands and the many misfortunes which befell him he showed a cheerful face to the world. The world would be a much happier place if everyone had his sunny temperament which made difficult tasks appear easy, without in any way underestimating their magnitude.

When it would have been far easier to reject the application for admission to an educational course of a student who had failed to comply with all the comparatively inelastic regulations required for qualification, William Myers opened the door for him with his golden key, "Well, we must do what we can for this man." Many an ex-service student of the College owes his post-war education there to Myers' fatherly sympathy. To see numbers of old students calling on him for advice; to hear the students' whole-hearted laughter at his jokes in class, accentuated by interspersed periods of tense silence; to read the letters of highly placed officials in the textile industry seeking his help either in technical matters or in suggesting suitable men for their staffs; to note the pleasure with which he gave out to all and sundry the fruits of many years of experience; to listen to his criticism or praise, given without fear, favour, or hope of reward, was to know something of William Myers. No one, be he saint or sinner, lord or commoner, educated or uneducated, could live with him without loving him; he endeared everyone to him and grappled his friends to his heart with hooks of steel. Having climbed the ladder of success, he never forgot those who had helped him to rise from rung to rung. Though he spoke his mind when occasion demanded he was really shy, modest, and acutely sensitive, with the result that his

pointed and forcible expressions always commanded attention and carried conviction.

The Textile Institute has been deprived of one of its staunchest supporters by his death. While living, he was always missed if absent from the Institute Committees of which he was a member, though this happened but rarely. His place in the activities of the Institute will be hard to fill, and one can only hope that those he has left behind will carry on his work in the same spirit in which he began it. His mind was in sympathy with both the practically and the theoretically inclined, and no one has done more to strengthen the bonds linking those who practise, profess, or teach textile technology.

Enthusiastic, untiring, and well-balanced in mind, he never spared himself, putting every ounce of his energy into his work. His sudden death, after he had occupied the chair of Textile Technology for but three weeks, came as a great shock to all who knew and cared for him, and leaves us with only one consoling thought—that joy in life is not measured in time units but in intensity of living. He lived as became him, actively assisting all who passed his way; he died as became him, in harness, leaving the memory of a big-hearted, kind-hearted, and true friend. —F. P. SLATER.

REVIEWS

Les Soies Artificielles. By A. Chaplet. Gauthiér-Villars et Cie, Paris, 1926 (248 pp. and Index. 3 fr. 75 c.).

This book gives a useful collection of literature mainly taken from patents. After giving an outline of the production of real silk and of the history of the development of artificial silk, the author describes methods of making solutions of cellulose in ammoniacal copper solution.

The information on viscose does not include such practical details as would enable a chemist not already familiar with this process to make viscose silk. The layout of plant is theoretical. Methods of making nitrocellulose and its solutions are given and the recovery of nitric acid and of the organic solvents is dealt with. The chapter on acetate silk deals with patents up to about 1912, that is before the time when acetate silk could be regarded as *un fait accompli*. The unsuccessful attempts to make artificial silk from materials of animal origin are described. Diagrams of plant used in the manufacture of artificial silk are given, but these are taken mainly from patent specifications. The bleaching, dyeing, and finishing of various kinds of artificial silk are dealt with. A method of dyeing acetate silk with diphenyl black is given and mention made of ionamines, azonines, and acetonines for the dyeing of acetate silk. Methods of stenosising artificial silk are given and a few tests illustrate the remarkable increase in wet strength claimed for the process, but the loss of elasticity produced at the same time is not an advantage. The properties of artificial silks of various kinds are dealt with fairly fully, and the statistics of production include the year 1924.

This book is more up to date than many books on the subject and covers a useful field, particularly relating to viscose and nitrocellulose. —W.H.

Artificial Silk and its Manufacture. By J. Foltzer. Translated from the French by T. Woodhouse. Third Edition. Sir Isaac Pitman & Sons, Ltd., London (248 pp. and Index. 21s. net).

The third edition is practically a reprint of the second.

The book deals mainly with the cuprammonium process, with which Foltzer is most familiar. The history of artificial silk is discussed and useful abstracts of a considerable amount of patent literature are given dealing with nitrocellulose, cuprammonium, viscose, and acetate silks. Notes are given on the dyeing of the various kinds of artificial silk and mention is made of the S.R.A. colours. The chapter on acetate silk is liable to give the impression that Celanese is the only kind of acetate silk known, which is of course erroneous. The properties of the various kinds of artificial silk are described and an account is given of methods of making artificial fabrics directly from cellulose solutions. The book is valuable to those interested in the manufacture of artificial silk by the cuprammonium process. —W.H.

GENERAL ITEMS AND REPORTS

Leeds University—Report of Departments of Textile Industries and Colour Chemistry and Dyeing

For fifty years the Clothworkers' Company has "sustained in unbroken continuity" its benefactions to the University in respect of the capital and annual expenditure of the Departments of Textile Industries and of Colour Chemistry and Dyeing. The annual report on the work of these departments made to the Company recently affords not only testimony to the cordial relations existing between the University and the Worshipful Company, but also to the comprehensive schemes of tuition and training in vogue at the University in the departments concerned. In view of the general appeal made by the University in October last the Clothworkers' Company have made a special grant of £18,300 towards the cost of structural alterations and additions to the machinery and equipment, while the annual maintenance allowance made by the Company is to be increased, during the next seven years, from £4,000 to £7,000 per annum. In all the grants from the Clothworkers' Company amount to a grand total of £243,292. It may well be said, in the words of a special resolution of the University Council, that "the Worshipful Company of Clothworkers will take rank amongst the chief founders of the higher education of modern England." Mention must not be omitted of a personal gift by Col. Stephenson Clarke, Past Master of the Company, of £1,000 for the endowment of a scholarship tenable in the Textile or Dyeing Departments. The departmental reports embodied in the general report are indicative of continued activity. In the Textile Department matters of interest to which reference may be made are the exhibit of work, British wools &c., prepared for the Yorkshire Show at Bradford, upon which Professors J. C. Ewart and A. F. Barker delivered addresses. Two special testing instruments have been produced for use in the drawing and spinning of woollen and worsted yarns. Researches are recorded into the "Nature and Properties of British Pedigree Wools," the "Extensibility of the Wool Fibre," and on "The Genetics of Wensleydale Black Sheep." A list of contributions to the technical and scientific literature is also given, as well as particulars of the students attending classes and the awards secured by them. In the Department of Colour Chemistry and Dyeing, as in the Textiles Department, a slight decrease in the number of students is recorded, but it may well be that trade depression has to be looked to for the real explanation of this, while on the other hand it is gratifying to record that the majority of students leaving the Dyeing Department have secured factory appointments. It is natural that the attention of the department has been turned to the problems presented by the dyeing of artificial silks, both alone and in admixture with other textile fibres. Gifts are acknowledged in respect of materials, equipment, and research scholarships, and a large amount of research work is reported, covered by publications of considerable interest, as well as records of work not yet completed. Satisfactory examination results and post-graduate progress are reported, as well as particulars of appointments obtained by students of the department.

British Launderers' Research Association

The annual report of this Association is the first to appear after the end of the initial period of five years that, in the case of such organisations, may be regarded as the inauguration and trial period. From Government funds, upon the advice of the Department of Scientific and Industrial Research, during the first five years the Association received £1 for £1 raised by the industry. The Association commences the second period upon a different basis, having to secure an annually increasing revenue in cash, not promises, from subscribers, to earn an annually decreasing grant from the department. The Chairman of the Council of the Association, Mr. D. E. Benson, in addressing the annual meeting of members, described the new, and previous conditions of Government support, and said that the minimum subscriptions for the year had already been secured, but that further effort was needed to secure the five-year average subscription, so that the gross annual income would not fall off when the grants from Government decreased. Dealing with the work of the Association, Mr. Benson pointed out

that the Director had ascertained that the present system of showing how much water was in a washing machine was unreliable, and had devised an arrangement which gave the required content within a reasonable margin of error. A project for the erection of a special building is described, wherein full-scale tests upon such soiled work as is received by the ordinary commercial laundry can be carried out in order to test the practical value of the results obtained from small-scale experiments. The report of the Director describing the work of the year draws special attention to the publication of a book, "The Control of Laundry Operations," and to a series of lectures delivered at district conferences of the Launderers' Federation. He points out that much work of a fundamental character is being and has been carried out by the Cotton, Linen, Silk, and Wool Research Associations that is of great importance to launderers, and which the Launderers' Research Laboratory would otherwise have had to undertake itself. Five reports were issued during the year dealing with the properties of certain soaps; the production and utilisation of steam in laundries; measurements of loads and detergents in the wash-house; hypochlorite bleach; and the design, construction, and use of a constant humidity room. Several patents have either been taken out or are pending, and in one case at least the device is to be marketed. The Director also outlined his programme of research for 1925-26, in which he includes a study of washing machines and the preparation and use of spirit soaps. Reference is made to the abstracting work carried out for this *Journal*, and to the establishment of an analytical and consulting department.

Cloth Construction

Mr. A. R. Tindall, of Bradford Technical College, speaking on this subject before the Bradford Textile Society, on Monday, 1st February, said that however well grounded he might be in the details of cloth construction, a designer would have little success unless he displayed natural adroitness in the handling of colour in application to the fabrics he sought to make. Related colours were, comparatively speaking, safe combinations to handle and could be relied upon, when judiciously used, to produce satisfactory patterns. Complementary colours, on the other hand, were considerably limited in their sphere of usefulness, due to their capacity for intensifying each other. Black and white, apart from their virtue in stripe and check effects, could be used with advantage to separate colours that partook of a large share of the same common element. In experimenting with related colours it would usually be found that when the need arose for having them contiguous, the most satisfactory effects were obtained when a shade was used in contrast with a tint. Graded colours, either in the form of a colour passing from light to dark or one colour grading into another, formed a useful basis for experiment in the hands of a cloth constructor endowed with artistic taste. It was well to bear in mind that shades formed reliable grounds and that a judicious use of brighter colours in blend and contrast would serve to smarten up the cloth. Where check effects were required they might be, according to requirements, balanced or unbalanced. In work of this kind the strength of the various colours was important; colour balance was essential, and to preserve this the strength of all should be as nearly as possible alike. Bright or expensive fancy yarns should never be used for bulk ground work; these should be used exclusively for embellishing the texture either in the form of stripes or checks. Cloth construction did not end with the weave, with the mathematics relating to the sett, or with the colouring; it must be a practical manufacturing proposition. This was a feature of the cloth constructor's work which required forethought and, in addition, an extensive knowledge of the looms at his disposal. Economic production was only possible when the goods were rapidly and correctly made, and in the making, three factors had to be taken into account, namely, the tenter, the weaver, and the loom. In the construction of woollen and worsted cloths too much stress could not be laid upon satisfactory finish in the development of the handle. Without a suitable raw material even the finisher could not develop the necessary handle. No finisher could repair the damage done to the raw material by excessive use of alkali in wool scouring, by an over-dose of acid in carbonising, or by carelessness in the operation of neutralising after carbonising. Under these circumstances the material took on a harsh, rough, wiry handle impossible to eliminate. No finisher could develop satisfactory goods if the cloth constructor

had made the initial error of setting his fabrics too narrow in the loom. In a case of this kind the finisher was allowed an insufficient margin between the grey width and the finished width. The best advice one could offer in considering the process of milling and its effect upon cloth was that under no circumstances should an attempt be made to force the operation. In conclusion, the lecturer said he was of opinion that the success of the French cloths lay not in the yarn but in the attention paid to mellow finish. Bradford spinners could produce more excellent yarns than the French, but because the French had adopted the old West of England methods—which included a good boiling of the cloths—they had scored. The crown of the cloth constructor's work lay in the hands of the finisher, and a satisfactory finish was summed up in the two words "quality" and "maturity." —M.

Mycological Work in Egypt during the Period 1920-1922*

Two-thirds of this volume deals with diseases of cotton ; the remainder will not be considered here.

Sore Shin—This widely-distributed disease of seedlings is described and a detailed account is given of investigations on the causal organism *Rhizoctonia solani* Kühn. From cotton seedlings suffering from sore shin three fungi were constantly isolated—*Rhizopus nigricans*, *Fusarium* sp., and *Rhizoctonia solani*. Extensive tests showed that only *Rhizoctonia* was parasitic. Infection experiments with plants other than cotton demonstrated that the fungus was able to attack seedlings of castor, sesame, pumpkin, lubia (*Vigna sinensis*), cabbage, lucerne, bamia (*Hibiscus esculentus*), earthnut, water melon, radish, lettuce, carrot, and pea. In addition, natural infections were discovered on seedlings of mustard and cress, and on mature plants of haricot bean, *Colocasia* sp., and bersim (*Trifolium alexandrinum*). The fungus can attack any of the above hosts when transferred from cotton and is also able to attack cotton when passed back from pea, bamia, earthnut, water melon, and mustard. Seedlings of wheat, barley, and maize are not susceptible. The morphological characters of the fungus in culture are detailed, and experiments on its growth relations are described. In culture, sclerotia are formed, and the size of these bodies in a single strain kept at constant temperature is considerably affected by the supply of moisture, food, and oxygen. This fungus is considered identical with specimens of *Rhizoctonia solani* from America and India, and with Ball's sore shin fungus described in 1905. Attempts were made to obtain the perfect stage of the organism, and a small number of spore-bearing basidia were produced when the fungus was growing as a saprophyte. This fertile stage is referred to *Corticium vagum* B. and C., with the reservation that this species contains many forms which may later have to be separated. No variety of cotton resistant to sore shin is known, and the causal fungus is of general occurrence in the soil throughout Egypt. Soil sterilisation for control of the disease is economically impracticable, and no chemical treatment can be generally recommended. Dressing with naphthalene lessens the amount of damage only under certain conditions of soil texture. The chief remedial measures are those which ensure rapid development of the seedling, since the fungus is most favoured by slow germination of the seed in a moist, relatively cool atmosphere. Good cultivation and draining, sowing not earlier than 15th March, and sowing at the right depth and position on the ridge, are therefore the most effective means of combating sore shin. When practicable, a rotation should be employed in which cotton succeeds wheat, maize, or a period of fallow. Cotton planted directly after bersim is specially liable to attack, as bersim is itself susceptible to the disease.

Root Rot—This disease is found in lubia (*Vigna sinensis*), beans, and cotton. The bast of affected plants is attacked and rotted, and sclerotia are formed in the dead tissues. A similar root rot of cotton occurs in India. The causal fungus is described and is named *Rhizoctonia* (*Sclerotium*) *bataticola* (Taub.) Butl. Successful inoculations with this organism were made on lubia and bean.

Angular Leaf Spot—A description is given of this disease (due to *Bacterium malvacearum*), which is not serious in Egypt. The term "anthracnose" is often

*By H. R. Briton-Jones, B.Sc., Ministry of Agriculture, Egypt, Technical and Scientific Service, Bulletin No. 49 (Botanical Section). Government Press, Cairo, 1925.

applied to *Bacterium malvacearum* infections of bolls, but the author has found no trace of true anthracnose (*Glomerella gossypii*) during three seasons in Egypt.

A Wound Parasite of Bolls—*Rhizopus nigricans* is a common wound parasite of bolls. This disease has been described in a separate bulletin.*

Fusarium Wilt—Wilted plants were obtained from Beheira and Sharqiya, showing a browning of the wood and presence of hyphæ in the vessels. From these specimens *Fusarium vasinfectum* was isolated, the cause of wilt disease in the United States. The morphological and cultural characters of this fungus are given. An extensive series of inoculations was made and successful infection was obtained on seedlings and young plants.

Physiological Wilt Disease—In a single locality on salty soil in Beheira Province wilting was brought about owing to protracted flooding of the ground, probably causing asphyxiation of the root systems. —R. W. M.

Rain Cotton in the Sudan†

Before the Manchester Literary and Philosophical Society, on 9th February 1926, a paper was read on the above subject by Mr. R. A. Wardle, M.Sc. Professor F. E. Weiss was in the chair, and the following is an abstract of the lecture—

The Southern Sudan is not an ideal area for cotton grown under rainfall conditions, owing to the shortness of the rainy season and to the uncertain distribution of the annual rainfall, but indigenous short staple cottons have been grown for at least 90 years, and experiments have shown that American long staple varieties can be grown successfully and will produce cotton sufficient in quality and quantity to warrant the establishment of cotton cultivation in the Central and Southern Provinces, thus enabling these areas to obtain a surplus of income over expenditure available for developmental schemes.

The Government policy is—

(*a*) In districts where native cottons have previously been grown, to encourage the cultivation of American long staple varieties by issuing free seed and by providing marketing and ginning facilities;

(*b*) In districts where cotton has not previously been grown, to establish experimental cultivation of American cotton at various centres of demonstration and propaganda, to issue free seed, and to guarantee a price for the crop produced.

Progress within the last two years has been rapid and prospects are very bright, despite the occurrence of problems concerning suitable varieties of cotton, dates of sowing, agricultural methods, interference of cotton with food crops, provision of transport, and ginning facilities, apathy of native tribes, &c. The ultimate limit of acreage under rain cotton will depend largely upon the extent to which road and rail communication between districts and ginneries can be developed.

*Bull. 19, Tech. and Sci. Service, Egyptian Min. of Agriculture.

†Report supplied by the Secretary.

THE JOURNAL OF THE TEXTILE INSTITUTE

Vol. XVII MARCH 1926 No. 3

PROCEEDINGS

Lancashire Section

Lantern Lecture and Social Evening held at the Institute, Thursday, 10th December 1925, the late Professor W. Myers presiding.

A MICROSCOPIST'S NOTES ON SOME TEXTILE FIBRES

Mr. Abraham Flatters, whose lecture on the above subject was to have been delivered at this function, was delayed by a railway accident, and was only able to give a synopsis of the lecture, during which a large number of interesting slides* were shown. In the course of his remarks Mr. Flatters dealt with the cotton plant, indicating its botanical classification—it belonged to the Mallow family, of the order *Malvaceæ*—and its geographical range—between 40° north and 30° south. Reference was made to the principal types of the cotton plant which were of commercial value. The protective character of the seed hairs was pointed out, and Mr. Flatters referred to other species of plants which had developed this characteristic. The lecturer then briefly described the reproductive process of the cotton plant, and in doing so exhibited several interesting slides illustrative of the phenomena described, Figs. 1 to 4. The lecturer then discussed the microscopical appearance of cotton hairs in transverse and longitudinal sections, and pointed out the range of variations to be discerned even in the hairs from one seed. He drew attention then to the differences that might be anticipated between cotton from different sources where soil and climatic conditions would vary widely. Turning to other fibres, Mr. Flatters said that it would take too long to describe the development and growth of them all, but that he would indicate the structure of the stem of a typical fibre-yielding plant, and as such he would describe the flax plant. In its early development a zone of growth or cambium ring arises on the inner side of which the wood of the plant is formed; on the outer side the bast fibres develop. The bast fibres are the true flax fibres, and in the economy of the plant their function is that of food conductors. The difference between the fibres seen in the plant before decortication and those from decorticated bundles of fibres was discussed, and attention drawn to the possible agents producing the differences—drying and contraction. Mr. Flatters suggested that the pits in the cell walls, which he pointed out in slides of sections of hemp and of ramie, were food storage devices; this method of food storage being a common feature of the seeds of many plants. The lecturer referred to a practical point in the decortication of

*A selection of these are reproduced here from prints kindly supplied by Mr. Flatters.

bast and leaf fibres, when he said that in their development the fibres of flax, hemp, and ramie are so intimately connected with the cell walls of the ground tissue of the plant that it appears to be practically impossible by any mechanical means to extract them from the stem or leaf without leaving scars on their exterior walls. In fact, if the coarser fibres be examined, it will be found that the original ground tissue still adheres to many of them, and cannot be removed without leaving scars. Turning to plants whose leaves yield fibres, Mr. Flatters instanced the family of *Bromeliaceæ*, the pineapple family, as probably supplying more marketable fibres than any other class, while of this order the two plants furnishing the finest and most easily separable fibre masses are known by the trade names of Arghan and Colombian Pita. The ultimate fibres from either of these plants when compared microscopically appear identical, and there can be no doubt that they are closely related if not actually from the same species of *Bromeliaceæ*, though grown under different local names. A series of slides was shown illustrating the points raised by the lecturer, and of these Figs. 5 to 10 constitute a selection.

Mr. Flatters next dealt with artificial silk, exhibiting slides of the four primary types, and said that he was indebted to Mr. W. Marshall, F.I.C., for information regarding the chemical composition of these types. He then described the four filaments illustrated, in the order of their introduction into commerce. In dealing next with animal fibres, the lecturer said that natural silk must take the premier position. Silk is the product of the silk moth, from the egg of which the actual spinner of the filament, the silkworm, emerges. It is a voracious feeder, becoming fully developed very rapidly, and at this stage spins for itself a protecting cocoon, from which, after passing through various stages of metamorphosis, the silk moth emerges. The silk fibre is a composite one, formed of two separate silk threads, held together by means of a gum-like fluid emitted by the silkworm at the same time as the true silk fibre. The silk is formed in glands occupying a considerable portion of the body of the adult larvæ. It is a viscous fluid ejected from the spinnerets in two distinct jets, the two filaments thus formed being at the moment of emergence coated over with the gummy fluid above referred to. On exposure to the atmosphere the silk hardens. Figs. 11 and 12 are reproductions of two of the slides exhibited by Mr. Flatters at this stage. Turning finally to hairs and wools, the lecturer pointed out that hairs are never entirely absent from the bodies of mammals. Two kinds of hairs might be distinguished, according to the strength and rigidity of the shaft, viz., contour hairs and woolly. Woolly hairs are delicate and curled, and surround to a greater or lesser extent the base of each contour hair. When contour hairs have a greater strength they become bristles, and when still stronger and thicker they constitute spines like those of the hedgehog or porcupine. The colour of animal hairs, the lecturer pointed out, is due chiefly to pigmentations in the hair walls or to a core of coloured fat permeating the fibre cavity, as for example, in the hairs of the llama or of the Cashmere goat.

The late Professor Myers, who presided over this meeting, expressed the thanks of all present to Mr. Flatters for his interesting lecture and for the valuable series of slides he had exhibited.

Luncheon-hour Meeting at the Institute, 26th February 1926, Mr. John Crompton presiding.

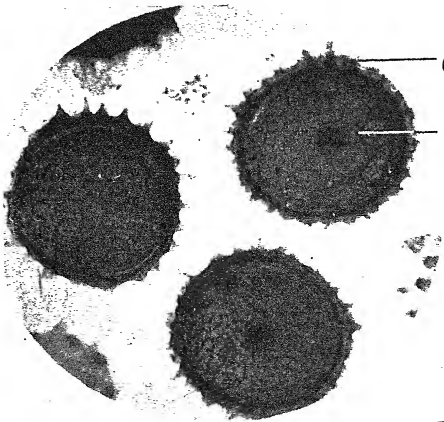
EMPLOYERS AND THE HOUSING PROBLEM

By Reginald Bruce, A.R.I.B.A.

When your Secretary asked me to contribute a paper on the subject for discussion to-day he very kindly sent me a copy of your *Journal* containing a lecture given a short time ago by the manager of one of the large mills. In reading this lecture it was very interesting to find that there are some who realise

Fig. 1.

Photomicrograph of three pollen grains from the ripe anther of the cotton plant, × 260. (*a*) The spiniferous wall, or *exine*, (*b*) the *intine* or male fertilising media.



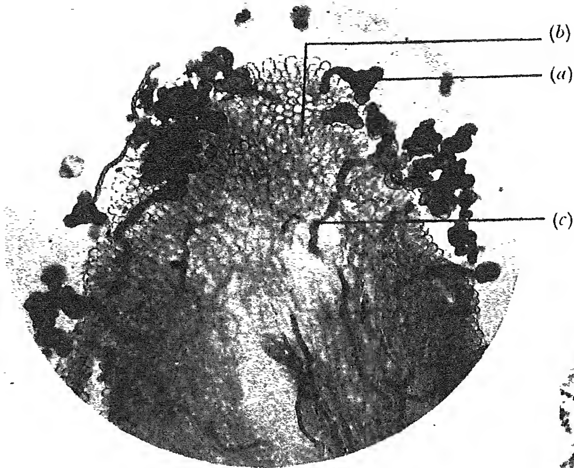


Fig. 2.

Photomicrograph of a longitudinal section through the stigmatic tissue of the Evening-primrose, × 35. (*a*) Pollen grains viewed from various points, (*b*) the stigmatic tissue, (*c*) fragments of pollen-tubes penetrating the stigmatic tissue on their way to the embryo-sac, or ovary.

Fig. 3.

that real progress in industry depends upon, and is directly related to, other branches of human activity. Mention was made of agriculture or food production and housing; there are also other important matters, such as transport facilities, public health, and so on. To-day, however, we are to consider only one of these, that of housing. It is not intended to deal with the national housing problem as it is generally understood—a matter which has passed through many vicissitudes, and is likely to continue to be a vexed question. Neither is it intended to refer to what has been done to provide houses for the working classes or the number of houses required to meet the shortage. It is sufficient for our purpose to accept the fact that there is a real need for many more houses to be built, not only to meet the demand of those who are unable to find houses to live in, and in consequence of which there is much overcrowding, but also to replace the thousands of dwellings which, although occupied, are totally unfit to live in. It is not, of course, suggested that employers can themselves entirely solve this problem, nor that it is expected they should. It is, however, suggested that it is in their interests to take an active part in the provision of houses for their employees.

Let us look at the matter from the following aspects—(1) The present position and the need for a broader outlook. (2) Its relation to health and efficiency of the worker. (3) Mobility or distribution of labour. (4) How employers can help to solve the problem.

It is only necessary to look back a few years to realise how greatly conditions of living generally have changed. Not long ago towns were not so large as they are to-day—people did not travel about to any extent, and they had a more leisurely existence—business was very largely centralised, and altogether there was much more independence of action. In recent times the whole method of living has been revolutionised. This is probably very largely due to the introduction of the mechanically-propelled vehicle and the intensification of mechanical appliances in the production of commodities of life and the carrying on of other undertakings. People are now enabled to move about much more than previously, and could, if other circumstances permitted, live farther from their work; goods can be produced more quickly, and their transport and delivery has been expedited and facilitated, and generally a saving of time and money effected. Furthermore, by the development of the telephone service and the introduction of wireless, the execution of business has been speeded up to an extraordinary degree, and towns and countries have been brought into closer contact. Although this has resulted in a broader outlook on life, there would appear to be in some respects a tendency towards isolation of interests—for one activity to assume an attitude of independence, and by so doing to lose sight of its relative position in regard to others and to the integral place it, in fact, occupies in the general sphere of activities of the country. The question therefor appears to be, can we afford to live in such a state of isolation, and can employers of labour afford to take no action or constructive interest in those matters which, although a casual thought might dismiss them as being foreign to the employers' individual concerns, are vitally related to them and essential to their own prosperity. Housing is one of such matters, and one which should occupy an important place in the employers' business purview.

The labour problem to-day is not only one dealing with such matters as hours of work and rates of wages; there are other things equally fundamental, and which must have due consideration in any endeavour to solve the difficulties contingent upon industrial expansion and the development of other activities. Modern conditions are continually raising the standard of living of the workers, and in the march of progress this must be fully recognised and appreciated. No longer is the worker content to work and live under the same conditions which existed a few years ago. He requires better houses to live in, gardens in which to grow food and flowers, open spaces and playing fields where he can

obtain bodily exercise, and the provision of facilities for mental recreation. He demands an entirely different environment to that which was provided for him during the great industrial period of a century ago, and, indeed, to which he is often subjected now. Environment is undoubtedly one of the fundamental attributes in the economical relationship between labour and production. It can without contradiction be said that much of the unrest and discontent amongst the workers during recent years has been largely due to the bad conditions under which they have been compelled to live—the horrible slums and squalid dwellings, the mean streets, and the absence of those amenities which affect the mentality and outlook on life. Is it not a convincing statement to make, that the better the worker is housed, the more pleasant and attractive his surroundings, and the greater the facilities for mental and bodily recreation, the more contented and happier he becomes, and, what is very essential, the more healthy? Is it not equally true that a healthy and contented man is more fitted to perform his daily work, and in consequence must it not materially affect both the quality of the work and the degree of output? This view was undoubtedly in the minds of those responsible for the establishment of some of our Garden Villages, as, for example, Bournville, the founder of which, having removed his works from the centre of Birmingham to a site outside the city, at the same time made provision for the proper housing and social life of his employees, and who subsequently stated that the venture had amply repaid him.

Mobility of labour is also an important factor in any endeavour to solve the problem of housing the workers. Before the war circumstances were such that there was no serious difficulty in transferring labour from one district to another as particular needs arose. It was not a serious matter for a man to remove his family to a district which offered work or where better conditions prevailed, because he was certain of finding housing accommodation. To-day the position is very different, and there have been many instances of work having been held up, and, indeed, business lost, owing to a shortage of labour in the particular locality, notwithstanding the fact that there was much general unemployment. The difficulty has been that amongst the number of unemployed there have been none of the particular skilled workers required, and owing to the shortage of housing accommodation it has not been possible to induce men to transfer from other districts. To do so would mean either a long journey every day from and to their homes, or for the man to go into lodgings and keep his home going elsewhere, neither of which can he afford to do. He would be much better off living on the dole. It is interesting to note that Mr. Churchill, in a recent speech, referred to this important aspect of the subject, and drew attention to the enormous loss that had accrued to labour as a result of this present day immobility. There is also a tendency at the present time for large firms to remove their works into more open country where there is room to expand, or to a situation nearer to the source of supply of some material needed for the production of their particular goods. The question of the housing of the workers, however, does not always seem to occur to them, or if it does it is put aside as being of no direct concern of theirs, but a matter for the speculative builder or the Government and the Municipality. Some help may certainly come in this way, but neither at the present time can be expected to deal adequately with the situation. I venture to say that the employer, if he is seeking to produce the best article and in the most economical manner, and if he would desire to hold his own in the increasing competition in the markets of the world, must realise that industry is only one component part in the economic organism of life, and that the housing of the employees is one of the matters which must have his due consideration.

What, then, can employers do to meet the housing needs—not with a view to solving the national housing problem, which must for some years be left to the country—but in their own interests and from the point of view of economic

living conditions of their employees? Of course the question of finance is always a troublesome one, but surely business men controlling large financial undertakings can find a way out, although in the matter of housing a large return in money cannot be looked for. The question as to whether it is a general advantage for workers to own their own houses or rent them is an interesting one, and in financing a scheme this aspect must be considered. Whilst there is perhaps much to be said in favour of the former, there are very few workers who possess sufficient means to buy houses, or are themselves able to raise the necessary money. Much can, however, be done by co-operative action amongst the employees themselves if properly directed or between the employers and the employees. Where the latter is done it cannot but help to bring about a better understanding, create an attitude of *esprit de corps*, and lead to greater contentment and general efficiency all round.

Now let us consider briefly a few of the methods by which employers can actively assist—

(1) Employers to undertake the whole of the work—acquire the land, have the plans prepared, lay out the streets, and, having erected the houses, sell or let them to their employees. The whole of the financial liabilities in this case to be met by the firms. With the high prices of building, however, and the difficulty of getting an economical return from letting, such a scheme is not likely to be readily accepted.

(2) To undertake the work in a similar way to the above, but obtain the financial assistance by means of subsidies and loans from the Government and the local authorities. A subsidy can be obtained from the Government under certain conditions, the amount depending upon whether it is intended to sell the houses or let them, such subsidy being in the form of a lump sum or an annual payment for a period of years. In addition to the subsidy given by the Government, the Local Authority may add a contribution from local funds if they are in a position to do so. Very considerable loans may also be obtained by bodies erecting houses through the local authorities, such loans being secured by mortgage on the property, and in the case of sale can be transferable to the purchaser if required.

(3) Co-operative action. The method of providing houses by co-operative action between the employer and employee is a very interesting and valuable one. It brings the two elements into close contact, and gives each a personal interest in the undertaking. The success of such a scheme depends upon the true spirit of co-operation amongst all concerned. The formation of what are called Public Utility Societies is quite a simple matter; a number have been established in the country, and have generally proved a great success.

An employer with his employees, or several firms joining together, or any other body, may form such a society, and take advantage of the facilities offered in the way of subsidies and loans under the Housing Acts. A Public Utility Society is one that is registered under the Industrial and Provident Societies Acts, and whose chief object is to provide houses, primarily for letting, but there is no hindrance to selling. Such a society is controlled by a committee of management, who decide upon a set of rules as to how the society is to be organised, and in the case we are considering would have representatives of the employers and also of those employees who desire to become tenants. Unlike a Building Society, whose function it is to loan money to enable people to purchase houses, a Public Utility Society is formed for the purpose of building houses. A society is limited in liability, and there is one important point, which is this, it may not pay a dividend higher than the rate fixed from time to time by the Treasury. Any surplus profits are expended on the improvement of the estate and for the benefit of the society's tenants. The capital required is raised by the issue of ordinary shares, loan stock, debentures, and loans. The tenants would also invest a small sum, and hold say at least one share in the society.

The underlying principle of such a scheme is to assist the employees to provide themselves with houses by joint effort, and as everything is done to their mutual advantage, it is in the interests of all to see that the scheme is carried forward on sound lines. It is important that the site should be well chosen from all points of view, and that the lay-out or planning of the site with roads, drains &c., and the designing of the houses, should be on sound economical lines. If the scheme is large enough, a hall for meetings could be erected, and provision should in all cases be made for recreation.

In conclusion, let me briefly refer to two or three instances where large employers of labour are making provision for housing in connection with their undertakings. An example of the employers themselves carrying out a scheme of housing is of a well-known firm who, unable to expand its works owing to all the surrounding land being built upon, has recently removed to a situation about three miles from the town where transport and other facilities are favourable, and are developing a large village for its employees. The firm has acquired the site, provided ample playing fields and recreation grounds, made provision for schools &c., and has already built 350 houses; many more are to be built. Private loans have been raised, and advantage taken of the Government subsidy. The firm is selling the houses to their employees, and, from a money point of view, at a considerable loss to the firm. The creation of such a village as this is surely a step in the right direction, and such a progressive firm cannot but realise that it is an undertaking which will result in an enormous benefit to themselves as well as to their employees.

Another example is of a firm who erected its works outside the town and provided for the housing of its employees on a site about a mile farther out. The head of the firm established a village Trust, the capital with which it was founded being a free gift. Under the terms of the trust deed all income derived from the village must be devoted to the improvement and extension of the village. The houses are let, not sold, and the income derived from the rents is spent on maintenance, provision of amenities, and the building of additional houses.

The last example to be quoted is that of one of the large railway companies. About three years ago this company, realising that the distribution of labour is with them a somewhat peculiar one, announced a progressive housing policy. The scheme is being worked through Public Utility Societies formed in a number of centres, the respective Committees undertaking the management and reporting to the company the number of houses required. The scheme is financed jointly by the company and the railwaymen, together with the assistance of the Government in the way of subsidies. The company acquire the sites and arrange for the plans to be prepared, and agrees to construct the necessary roads and sewers, and to lease to each society a developed site at a ground rent calculated at 4% upon the apportioned capital outlay. The company also undertakes to advance 90% of the capital expenditure upon the houses, the loans being repayable within a period of 50 years at interest of 4%.

These examples are referred to just to show that some employers are realising what is in fact their responsibility. In such a short time at our disposal it has not been possible to go into details or do more than just indicate how directly and fundamentally the matter of housing is linked up with industry, and to suggest some ways in which employers can deal with it.

Discussion

The Chairman, in calling upon Mr. Bruce to read the foregoing paper, said that it came at the close of a series of lectures dealing with the relations between the masters and the operatives and the training and general conditions of employment of the latter. All were very desirous that the conditions of labour in textile factories should be as perfect as possible. They were also, however, concerned with the conditions obtaining outside the factory. While it was true that the employer had not got money to spare to build houses for his

workpeople, yet he was quite willing to serve in any other way he possibly could. From this point of view he thought it was wise that they should have an address from Mr. Bruce, whose lecture he was sure would prove very helpful and suggestive in the matter of the solution not only of immediate problems but of those of the future.

Following the reading of the paper, the Chairman said that Mr. Bruce would perhaps excuse them if they regarded the matter from the point of view that their works were already established. The majority of employers in the textile industry were anxious to establish the very best possible housing and working conditions for their operatives. Personally, he felt that it was their duty to do so. He had had some experience in the provision of housing accommodation, and he would advise employers to be very chary as to action in that direction. It was bad enough nowadays to cope with the difficulties of management in the works, but if there was any appearance that certain individuals or sections were being favoured by having better houses, or more attention in their houses than others, the problems of management would be much more complicated, and jealousy would be introduced. Employers experienced enough difficulties in finding out the best operatives and guiding them right, from their entrance into the works from the schools, and in finding out what they were best adapted for, without troubling too much about the conditions outside. Of course many employers in the textile industry were vitally interested in the educational problem, which he thought should be managed principally by outsiders. He had the pleasure of drawing the attention of the Institute to the advisability of continued education between the ages of 14 and 16 by allowing young people to attend technical classes or continuation classes each third week, or one-third of their time. It was, however, not of much avail for one firm to do it; if it was beneficial for one it was beneficial for all. The Lancashire County Council would willingly co-operate with manufacturers in promoting such schemes. The financial side of the housing problem was very serious. There were, of course, plenty of instances in foreign countries where employers had built houses for their workpeople. In the United States, some fifty years ago, a person could not put up a works without having to provide housing accommodation as well. Unfortunately, such accommodation usually took the form of barrack-like structures. Anyone who went to Fall River now would see almost worse slums there in connection with these barrack structures than they would in certain parts of Lancashire. It was important that there should be no discouragement of active co-operation between the employer and the employee, and it was distinctly advisable that the employee should be able to purchase his own house. This practice obtained very largely before the war at Great Harwood and other Lancashire districts. Formerly workpeople could buy their houses for about £150, but now they would have to pay £500 or £600 for a similar type of house.

Col. F. R. McConnel mentioned that he had had the management of at least two concerns which had to provide housing accommodation for their workpeople. The problem of providing houses of the highest possible comfort and efficiency was an exceedingly interesting one. Both the cases he referred to were in country districts, where they had not to deal with the trouble and expense of providing street paving, large sewers &c. As far as making such provision in country districts was concerned, he was a great believer in simplicity. A plentiful supply of good fresh water was necessary, and if there was ample room and air space an immense amount of money could be saved without detriment to the health of the people. Modified methods of main drainage could be adopted. It was desirable, in certain trades, to have the houses not only economically built but capable of being removed. He had rather a feeling that the best way to deal with a textile village would be to burn the whole lot down in about 20 years and start again on fresh ground. It would be very much more healthy, but it could not always be managed. To elaborate rules and conditions with

regard to the building of "permanent" houses was a mistake. Some mills had been built for all time—fireproof material, and all the rest of it. Perhaps they had already been up for 50 years, and would last for another 50 or 100 years, possibly to the horror and disgust of their owners, because they could not use them properly. The same consideration applied to dwelling-houses; they should not be too permanent. They should be inspected to see that they were kept in sanitary condition, and then there should be plenty of fresh houses so that anything approaching a slum could be demolished. Housing was at least as important as education. It was the duty of employers to press forward the supply of fresh, comfortable houses for the working classes, and, moreover, it would prove to be a remunerative investment from many points of view.

Mr. T. Fletcher Robinson inquired whether in regard to utility societies it was possible to obtain loans at a lower rate of interest than those from the Government, apart from subsidies. If so, it would help the Government considerably.

Mr. Bruce said that was the case.

Mr. E. N. Whittaker asked what was the type of model house Mr. Bruce would recommend ?

Mr. Bruce said it was rather a difficult question to answer. It must be a type of house which would meet the needs of the people, and it was not possible to give a broad general outline of what was needed by them. What was required in one district did not apply to another. Generally speaking, a house should have a very large living-room, and if the people wished to have a parlour they should have it by all means. There should also be a very ample kitchen and three bedrooms. A society such as he had described generally understood the needs of those for whom it was catering. The tenants were becoming the owners of the property, and if certain of those tenants wanted two bedrooms only, because of having no children, that could be arranged. In his opinion, the working part of the house was the most important.

Mr. W. P. Crankshaw said he had lately had the privilege of inspecting a large new artificial silk factory erected in an entirely non-textile district. Railway and chara-a-banc transport arrangements had now been instituted by which the company were enabled to draw upon the available female labour of the county.

Mr. Bruce, in reply, said that transport was a matter which industry must always consider in relation to progress. Many mills were placed in such situations that it would not be possible to house the workpeople within a distance of two or three miles. Railway companies now gave a great deal of consideration to such positions. There was a tremendous waste of time and money due to congestion in big town centres. For instance, coming from Burnley to Liverpool by road a great deal of traffic came through Manchester on the Liverpool Road *via* Warrington. Hours of time were wasted in the central parts of Manchester owing to traffic congestion, and the non-provision of by-pass and skirting roads. Employers must take a greater interest in such matters, and force local authorities to make adequate provision for through traffic.

Mr. W. Bailey, in moving that the best thanks of the meeting be accorded to Mr. Bruce for his excellent paper, and also to Mr. Crompton for presiding, said it was remarkable that the people who lived in the slums of such places as Belfast and Glasgow were not really worse than they were.

Mr. T. Fletcher Robinson seconded the motion. The housing question was one in which the textile industry was deeply interested. Money was very difficult to raise, but, after all, a great deal could be done by those who had a deep interest in the work. Much might be done by the scheme of Committees mentioned by Mr. Bruce, while there were, in addition, Government loans and subsidies to be considered. In order to ensure the mobility of labour it was not too much to ask that the employer should build houses to be let at reasonable rentals. People were having to travel from such places as Bolton to, say, Oldham, to follow

their employment, with the result that much expense was incurred. He then put the vote of thanks, which was carried with acclamation.

Mr. Bruce, in responding to the vote, referred to the question of the mobility of labour. Unfortunately, local authorities in devising housing schemes were not accustomed to consult with employers as to where houses should be erected, so that accommodation was not always provided in the best position from the worker's point of view. The worker always desired to be as near his employment as possible, all other conditions being favourable. It was for this reason that he urged leaders of industry specially to interest themselves in the matter. With regard to jealousy existing among the workers, if a firm undertook to do the work in the manner outlined in the paper, the whole plan would be dealt with co-operatively. The workers would be concerned personally, because they would be the tenants and/or the owners of the houses if they were members of the society. If they were not, they would be out of the scheme and have no concern with it; so that there would be no question of jealousy or favouritism as between the employer and the employees. There was a great deal of force in the argument that houses should not be built to last for an unduly extended period of years.

TEXTILE SOCIETIES AND KINDRED ORGANISATIONS

VISIT OF DELEGATES TO BRADFORD TECHNICAL COLLEGE

On Saturday, 24th February, in place of the usual conference of representatives of Textile Societies and Kindred Organisations held at least annually, a visit took place to the Textile Department of the Bradford Technical College, when a company of about fifty attended, representing various textile societies in Yorkshire, Lancashire, and the Midlands, and also mill managers' associations and the Federation of Managers' Associations. These gatherings were promoted a few years ago by the Textile Institute, which has continued to provide the secretarial services in connection therewith. The Bradford Textile Society offered a cordial welcome to delegates to visit Bradford, and the Principal of the Technical College extended an invitation for inspection of the textile department at that institution. The delegates were met at the College by the President of the Bradford Textile Society, Mr. Sydney E. Illingworth, who extended to them a hearty welcome. He said he was glad to witness so representative a gathering of delegates. Bradford was always pleased to welcome those who were connected with the textile industry of this country or of the Empire. In Bradford a great deal of time was spent in bringing out new cloths, and he hoped the delegates would not go away without leaving some record of their opinions as to what was taking place in the College with a view to helping the industry.

Principal H. Richardson also welcomed the delegates, and said their relationships with the Bradford Textile Society were exceptionally close, and on that account they regarded it as a great privilege to entertain guests from other societies on an occasion of this description. In that department of the College they were mainly concerned with the instruction of young people who had to earn their living at the same time that they got their training. It was only by the linking up of the various organisations that the best service to the industry could be rendered. Progress was also dependent on the general support and goodwill of those directly concerned with the industry; at the College they would welcome constructive criticism.

Professor E. Midgley, head of the Textile Department, explained the course of inspection decided upon, and the delegates then viewed the various sections of the department in suitable groups. Subsequently the delegates were entertained to tea by the Bradford Textile Society, when Mr. Illingworth presided.

The minutes of the previous meeting (17th October 1925) were approved, and it was agreed that the next conference should take place in October next, the details being referred to a small sub-committee comprising Messrs. John Robinson (Textile Institute), Henry Binns (Bradford Textile Society), and the General Secretary of the Textile Institute (J. D. Athey). After tea, Mr. J. H. Dawson (Brierfield), representing the National Federation of Managers' Associations, referred to the inspection of the College, and said he had come to the conclusion that with respect to machinery equipment the position at Bradford was relatively highly advanced. Even in regard to high drafting, about which so much was heard in Lancashire at the present time, it seemed to him that in certain machines installed in that College they had already got quite definite introduction of the principles connected with high drafting. As delegates, they had been invited to offer constructive criticism, but he was afraid that such criticism could better come from Yorkshire to Lancashire rather than from Lancashire to Yorkshire. He was forcibly struck with the accommodation for instruction as to raw materials. He understood that there were seven class-rooms, and that a full course was offered in regard to raw materials. It would not be a bad thing if something of the same kind were in operation in the cotton industry area. The only possible suggestion he might possibly offer would be that the cinema might be introduced in a department like that which they had inspected, and slow motion films provided for the purpose of instruction in machinery motions.

At this stage of the proceedings, Mr. Ernest A. Herbert, Chairman of the Executive Committee of the Bradford Textile Society, took the chair, as Mr. Illingworth was obliged to leave. He said that meetings of this description were exceedingly helpful, and Lancashire and Yorkshire representatives should get more together than they did.

Mr. John Chamberlain (Leicester Textile Society) then spoke, and said that so far as his own district was concerned their chief difficulty was to get day-time students, and the various textile societies should be interested in the complete problem of technical instruction.

Councillor B. Walton (Todmorden Textile Society) also spoke, and said the College was certainly exceedingly well equipped with machinery. With regard to technical instruction generally, the teaching profession was mobile, but the machinery was not, and this meant that students in many of our smaller districts were labouring under a very big handicap, inasmuch as they had to pass the same examinations as those students who secured the advantages of the better equipped institutions. He did not know whether anything more could be done in regard to travel facilities for students to attend the more completely equipped colleges.

Mr. E. C. Parker (Nelson), representing Burnley and District Managers' Association, said he was convinced that a meeting of this description enlarged their field of conception, and it was only by co-operation and interchange of views and ideas that the industry as a whole could be assisted. Exchange of information from one branch of the industry to another must be beneficial.

On the motion of Mr. John T. Stokes (Leicester Textile Society), seconded by Mr. G. W. Haigh (Halifax Textile Society), a hearty vote of thanks was accorded to the Bradford Textile Society and to the College officials and staff for their hospitality and grant of facilities, Mr. Herbert, Professor E. Midgley, and Mr. J. Dumville responding.

London Section

Discussion Meeting at the Institute's Rooms, 38 Bloomsbury Square, W.C.1, 1st February 1926. Chairman, Mr. T. Bray.

THE PRODUCTION OF DESIGN IN FABRICS

Mr. E. B. Fry, who opened the discussion, stated that he intended to discuss the production of design in fabrics, and for that purpose to show a series of lantern slides, explaining each in turn. He suggested that "pattern" would have been a more correct description than "design" in the title of his paper, as he intended to deal with the subject more from the constructional point of view than from the art or design standpoint. He hoped to show how the production of pattern affected the economical manufacture of fabrics. He proceeded to deal with elementary principles underlying all types of weaving, illustrating each point with lantern slides. He first described the earliest and most primitive types of weaving, going from thence to the more elaborate hand looms, the simpler power looms, and so through the whole range of tappet, dobby, and jacquard looms, pointing out that each progressive stage marked the control of an increasing number of threads, so making possible the production of more and more elaborate designs. Simple weaves, such as plain twill, diagonal, sateen, repp, crêpe, &c., were shown, and the various arrangements of threads for the production of suitable designs were demonstrated. The question of the relative speeds of various types of looms and the relative proportions of warp and weft were discussed from a point of view of economical production. The use of fancy yarns, such as grandrelle, gimp, loops, and slub yarns, were demonstrated by means of photographs of fabrics. Various methods of printing, both on the warp and on the completed fabric, were shown, and the various methods of introducing design by dyeing, cross dyeing, and combined printing and dyeing were explained. The lecturer also dealt with imitation and real embroidery, showing how closely the loom could copy the embroidery machine. He also explained the characteristics of construction of double and multiple cloths, illustrating each example with weave diagrams and photographs of the fabrics, including backed cloths with two-colour effects, mantle cloths, quiltings, hose pipes, pillow slips, canvas bags, &c.

In the discussion which followed the lecture, the question was raised as to whether the embroidery in many of the beautiful Indian shawls was not really the product of the embroidery machine. Mr. Howard stated that in many years' experience of this type of fabric, he had to confess that it was sometimes impossible to tell whether a shawl were hand embroidered or not.

In answer to a question, Mr. Fry explained how crêpe effects are produced, by weaving with a heavily dressed hard twisted yarn, and subsequently removing the dressing in the finishing process, thus allowing the yarn to crinkle up.

Mr. Bray, in moving a vote of thanks to the lecturer, stated that he had never had the pleasure of witnessing so fine a collection of lantern slides on this subject, and he must heartily congratulate Mr. Fry on the excellence of his illustrations.

Mr. Fry, in reply, stated that he was a great believer in the use of lantern slides for papers of this type, and he hoped that in the future more use would be made of the projecting lantern by the London Section.

(The projection lantern was given by Mr. Fry to the London Section in February 1924. This meeting was the first occasion on which it had been used.)

NOTES AND NOTICES

Meeting of Institute Council

At the last meeting of the Council of the Institute, on Wednesday, 17th March, the attendance was unusually small owing to a variety of exceptional circumstances. Mr. John Crompton (Chairman) was abroad, Mr. W. Frost (Hon. Secretary) was in London, partly on account of Institute business, whilst Mr. John F. White (Bradford) was unable to be present owing to indisposition. Mr. Oscar S. Hall, who attended after a rather prolonged period of absence from Council meetings, was voted to the chair as the senior member present. The business was considerable, but the proceedings were not protracted. The Secretary presented a list of nominations received in connection with the Annual Election of Council and Vice-presidents. In the latter connection, Messrs. John Crompton and H. P. Greg were nominated by the Council, and as there was no additional nomination the Council added the name of Mr. J. H. Lester. There are three vice-presidential vacancies and three nominations, so that there will be no ballot as to Vice-presidents. In the case of the Council itself, however, for the ten vacant seats twenty nominations were returned, so that an election by ballot will take place and ballot papers will be issued in due course and in due time for return prior to the Annual General Meeting on the 21st April. The Secretary also reported that for the presidency the invitation of the Council to Mr. William Howarth, of the Fine Cotton Spinners' Association, had been accepted and a letter from Mr. Howarth was appreciatively received.

Institute Diplomas: Fellowships and Associateships

The Council had before it, at the same meeting, a further instalment of recommendations of the Selection (Diplomas) Committee for admission of applicants to the Fellowship and Associateship of the Institute, and the list was approved without exception. This was the third instalment, making a total of 105 awards—74 Fellowships and 31 Associateships. The names will be announced at the Annual General Meeting, 21st April, and in the case of Mr. J. H. Lester, who is to receive the second Certificate of Fellowship—the first having already been awarded to the existing President (Mr. John Emsley, J.P.)—a special presentation of the certificate will be made at the meeting. It may be here mentioned that the total number of applications for Diplomas at the time of the writing of this paragraph has reached 190, and the work of the Selection Committee, as may be readily imagined, has been most formidable. The Committee meets with great frequency and all applications are fully considered, whilst decisions arrived at are presented for confirmation at a subsequent meeting, before any definite recommendation is sent forward to Council.

Proposed Meeting at Dunfermline

At the time of the Institute's visit to Dunfermline, in connection with the Annual Conference held at Edinburgh last Whit-week, the suggestion was made that during the present session a further meeting might take place at Dunfermline of a more or less local character. Negotiations have been proceeding in the course of the last few weeks, and it was hoped to arrange for a lecture on the subject of electrical driving. A disappointment was experienced in regard to overtures for the contribution of a paper, and ultimately it was decided on a further recommendation from Dunfermline that the meeting should not take place until the very early part of next session. A lecture has been arranged for, however, and definite engagement arranged for delivery at the later date.

The Publications Committee of the Institute

At this month's meeting of the above Committee, a suggestion was made that a very interesting paper on "The Problem of Unemployment," by F. Wigglesworth, might either be published in full or in extended abstract in this *Journal*. It was decided that to publish in full a paper that had already appeared in another journal was contrary to the policy of the Committee and involved, moreover, unnecessary expense. The third instalment of the article not having yet appeared an abstract was not possible, and other arrangements have been made. By the courtesy of the Editor of the *Journal of the Swedish Chamber of Commerce for the United Kingdom*, in the January, February, and March issues of which this article appears, members of this Institute interested in this subject may receive copies of the issues containing the article (as long as the supply lasts) on application to 14 Trinity Square, London, E.C.3.

By a misunderstanding the line indicating that No. 10 and No. 11 of the Transactions of the Institute published in the February issue of this *Journal* emanated from the British Research Association for the Woollen and Worsted Industries was omitted. Apologies have been made to the Association and it is hoped no inconvenience will arise from the omission.

Association of Special Libraries and Information Bureaux

A business meeting, at which it is proposed formally to inaugurate the Association of Special Libraries and Information Bureaux, will be held at the Institution of Mechanical Engineers, Storey's Gate, S.W.1, at 2.30 p.m. on Monday, 29th March 1926. All interested are cordially invited to attend. The Association is being formed to facilitate the co-ordination and systematic use of sources of information in science, industry, commerce, and public affairs generally; when fully developed it will function as a clearing house for those wishing to get into touch with specialised knowledge. The Association's first activity is to be the compilation of a Directory of Special Libraries and Information Bureaux in the British Isles. No complete list exists at present, and the Directory should therefore prove a valuable book of reference; the work will be authoritative and will indicate the sources where both scientific and non-scientific information may be obtained; the entries in the Directory are to be carefully annotated throughout. The whole movement is deeply indebted to the Carnegie United Kingdom Trustees, who in addition to setting aside the sum of £1,500 to assist the Association in the first two years of its work, have now generously undertaken to defray the cost of compiling the Directory. It is anticipated that something like a year will be occupied in collecting the necessary data. Those in touch with special sources of information and willing to collaborate with the Association in building up the Directory are asked to communicate with the Organising Secretary, 38 Bloomsbury Square, W.C.1, from whom further information may be obtained. Two very successful conferences have been held, at Hoddesdon (1924) and at Balliol College, Oxford (1925). The proceedings have been published, and copies can be obtained (price 7s. 6d. for the two reports) from the office of the Association, 38 Bloomsbury Square, London, W.C.1. This Institute is represented on the Committee of the A.S.L.I.B. by Dr. J. C. Withers, Chairman of the Publications Committee.

Institute Membership

At the March meeting of the Council of the Institute, the following applicants for membership were elected—Cyril O. Clark, York House, Belle Vue, Bradford, Yorks. (Textile Chemist and Technologist); Charles F. Foulds, "Overdale," Colne (Cotton Manufacturer); Rufus Gaunt, 60 Bent Lane, Prestwich, Manchester (Research Chemist); Harry Kenyon, 6 Victoria Terrace, Sandy Lane, Leyland (Loom Overlooker); John W. Kenyon, 6 Victoria Terrace, Leyland

(Mill Manager); George H. O'Brien, Lloyds Bank Buildings, King Street, Manchester (Patent Agent); Walter Stokes, Lal-imli Mansions, Cawnpore, India (Manager—Worsted Drawing, Spinning, Twisting, &c.); Katsuzo Tatsuki, 9 Herbert Street, Whitworth Park, Manchester (Teacher of Chemistry); A. Whitehead, 3 South Parade, Manchester (Merchant and Shipper); Brook Crabtree, 79 Honeywell Road, Wandsworth Common, London, S.W.11 (Examiner of Cotton and Linen Textiles); May Gwendoline Douglas, 60 Nimrod Road, Streatham, London, S.W.16 (Silk Instructor); Eirylys Ruth John, 242 Victoria Road, Romford, Essex; Harold J. Stewart, 7 Mallinson Road, Wandsworth Common, London, S.W.11 (Shipping Clerk—Textiles); Samuel A. Williams, Westminster Day Continuation School, 66 Horseferry Road, London, S.W.1; M. A. Whitney, 27 Warwick Lane, London, E.C.4; Charles Barker, 1 Booth Street, Manchester (Director of Greg Bros.); Edward Hall, Messrs. E. Hall & Bro. Ltd., Whaley Bridge (Bleachers); Morris Hastie, 52 Waverley Road, Bradford (Textile Chemist); D. Hill, 34 Longton Grove, Sydenham, London, S.E.26 (Student, School of Economics); F. W. Hoyle, 19 Chenistoun Gardens, Kensington, London, W.8 (Buying Dept. of Clothing Retail Store); A. E. Mellor, Greg Bros. and Co. Ltd., 1 Booth Street, Manchester (Company Director); Khim Moung, College of Technology, Manchester (Assistant Spinning Master); Pei Y. Sheng, Dobson & Barlow, Ltd., Bolton (Textile); Lancelot Stell, 1 Fardene Terrace, Silsden, near Keighley (Efficiency Manager to Messrs. F. Willey & Co. Ltd.).

Publications Added to the Institute Library

January—March 1926

Books

Les Soies Artificielles. Second edition. (Gauthier, Villars & Cie.)
Artificial Silk and its Manufacture. J. Foltzer (Sir Isaac Pitman & Sons, Ltd.).
Report of the British Association for the Advancement of Science 1925.
American Society for Testing Materials. Proceedings of the Twenty-eighth Annual Meeting. Parts I. and II.
Concerning the Bleaching Industry. The Bleachers' Association 1925.
Michigan State Board of Agriculture. Thirty-seventh Annual Report of the Experiment Station 1924.
The Silk and Rayon (Artificial Silk) Directory and Buyers' Guide of Great Britain. (John Heywood, Ltd.)
Linen, Hemp, and Jute Trades Directory 1926. H. R. Carter.
Chemist's Year Book 1926. (Sherratt & Hughes.)
Cotton Year Book 1926. (Marsden & Co.)
Wool Year Book 1926. (Marsden & Co.)
Textile Manufacturer Year Book 1926. (Emmott & Co.)
Incorporated Accountant's Year Book 1926.

REVIEWS

Bibliography of Bibliographies on Chemistry and Chemical Technology, 1900-1924. By Clarence J. West and D. D. Berolzeimer. Published by the National Research Council, Washington, D.C., as their Bulletin No. 50 (308 p., $2.50).

This work is composed of the following sections—General Bibliographies, Abstract Journals and Year-books, General Indexes of Serials, Bibliographies of Special Subjects, and Personal Bibliographies. As the title indicates, the work is a compilation of bibliographies published either separately or at the end of books or magazine articles, or as footnotes to the same, on the numerous aspects of pure and applied chemistry. Each entry gives name of author or compiler, title, and place of publication. The majority of the entries state the number of references, thus giving an indication of the completeness of the particular bibliography. The entries are classified under the proper subject headings, alphabetically arranged. The duplication of individual entries has been largely avoided by the use of cross-references. Although no claim is made for the completeness of the compilation, it is believed that the work will furnish a convenient starting point for any bibliographic search.

Linen, Hemp, and Jute Trades Directory. H. R. Carter, Belfast (276 pages, 8s. 6d.).

This publication is a comprehensive and useful collection of all the multifarious branches of the above three Industries and Subsidiary Trades connected therewith. The volume is divided into three chief sections—(1) Linen, (2) Hemp, including "Sisal," and (3) Jute—and concludes with a useful list of technical publications on textile subjects.

The linen section has been carefully classified into its correct sequence of industries and separate trades. These include flax seed merchants, agents, and exporters of all the countries of the world, and a few of the chief flax cultivators in the British Isles, the Colonies and Protectorates, and Foreign countries. These are supplemented by a long list of flax scutchers, while the flax and tow merchants of Ireland, England, and Scotland, together with those of the chief European countries, constitute a formidable and final list of all firms interested in the preparation and distribution of the raw material. Next follow fourteen pages in alphabetical order of flax and tow spinners in the British Isles, Europe, and the United States of America. The manufacturers of linen thread are likewise listed. Forty pages are devoted to the classification of linen manufacturers throughout the world. These are grouped and returned under the specific denominations of general linen, damasks, handkerchiefs, dress linens, tablecloths, lint, flax hose pipe, and webbing and tape manufacture. Yarn and cloth bleachers, dryers, and finishers complete the list of those interested in the final product of woven saleable linens. Upwards of fifteen pages are reserved to enumerate the list of linen merchants. This linen section is closed

with lists of machine makers for flax scutching, preparing, and spinning, including hackling, carding, and combing, bobbin makers, and mill furnishers.

The hemp and jute trades are likewise treated. The book has been carefully and well indexed, and should prove of much advantage for reference to all engaged or interested in the above trades. —F.B.

Concerning the Bleaching Industry. Compiled by Sir Alan J. Sykes. Published by Bleachers' Association, Limited.

This is a commemorative volume of a very attractive kind and is to mark the completion of the first quarter of a century's work of Bleachers' Association, Limited. It consists of an historical outline of bleaching practice; an account of the Association's formation and development; a description of the new headquarters of the Association—Blackfriars House; and some valuable particulars of bleachworks past and present. The historical section is most interesting and it is aptly said that "the history of bleaching is the history of civilisation." In this country at any rate it is undoubtedly so. As early as 1322 four bleaching grounds existed at Curmshal (Crumsall), and from that time onwards records exist which clearly indicate how Lancashire by an association of circumstances became the "cotton county of the British Isles," and thus, by necessity, the centre of the bleaching industry. Opposition to the use of cotton, as being inimical to the interests of sheep farmers and woollen merchants, came to a head in 1700, when it was enacted that the use of cotton was forbidden and the bleaching industry also made only such progress as the stern eye of the law allowed. This historical outline could freely be quoted if space permitted, as it is lucidly written and presents matter of great value to those interested in this aspect of industry. Perhaps a cheaper edition of the work could be put on the market, thus becoming available to a much wider public. Reference must be made to the series of "episodes" which are included in this section of the volume, and which deal with such subjects as the early Manchester Chamber of Commerce, selling a secret process, croft breaking and the infliction of the death penalty for so doing, and the Society of Bleachers out of which the present Association arose. Turning to the next section of the book it is worth noting that the portrait reproductions of the Chairman and other officials of the Association are exceptionally good. The account of the functions and activities of the Association in their trade aspect, as well as in regard to their welfare and recreational aspects is a record of which those responsible may be proud. A description of the site of Blackfriars House and its owners, so far as they can be ascertained, introduces the next section of the volume, and a brief account of "the Bleachers' " headquarters does no more than justice to a building that is rightly claimed to be worthy of the "best architectural traditions of Manchester." With the story of some early bleachworks and some illustrations of bleachworks past and present, the volume concludes. The work is noteworthy, too, in respect of the reproductions of various ancient documents, such as the title page of "Smegmatalogia," a book on the art of making potashes and soap and bleaching of linen; the original licence, dated 1815, granted to Slaters, of Dunscar, to manufacture "oxygenated muriatic acid," as chlorine was then known; the original agreement between sundry employees of Thomas Ridgway & Co. to form a building society; and an indenture between two "whitsters" and an apprentice, executed in 1791, being not only well produced but of definite historical value. The binding and general appearance of the volume is excellent, but there is such a liberal use of red borders, initials, and emblems in the first dozen pages that the pleasure afforded by the first page is proportionately diminished as repetition reveals itself. There can be no doubt that this souvenir will be treasured by all recipients.

—H.L.R.

Illustrated Technical Dictionaries: Volume XVI, Weaving and Woven Fabrics. Edited by Alfred Schlomann. Published by Lewenz & Wilkinson, Ltd., Victoria Street, London, S.W.1 (710 pp. including Index in six languages, 41s. net).

This volume with Volumes XIV., Raw Materials, and XV., Spinning, completes, for the time being the textile series of these admirable dictionaries. There can be no question that these books have been urgently wanted for years, and there should be a ready sale for the three volumes. It is announced that a fourth

volume, dealing with Bleaching, Dyeing, Printing, and Finishing, as well as such subjects as Knitting, Hosiery Manufacture, Embroidery, and Sewing Machines, is in course of preparation. It might be suggested to the compilers that a similar service for Laundering and Dry-cleaning would round off the series in a most adequate manner. The highest of praise is due to the compilers for the detailed nature of the work and for the wealth of illustrations. It would reduce the value of the work many times were these latter not provided. The compiler records his thanks for the services of Professor H. Brüggemann, Mr. Oscar Hall, Mr. H. I. Lewenz, and Mr. Scott Taggart for the ungrudging pains they have taken in the exceptionally difficult work connected with these dictionaries. There can be no hesitation in saying that the result of the work of all concerned is a valuable and excellent series of reference works likely to be of great use to the whole industry. —H.L.R.

The Silk and Rayon (Artificial Silk) Directory and Buyers' Guide of Great Britain. By Arnold H. Hard. Published by John Heywood, Ltd., London and Manchester (268 pp., 21s. net).

This directory has been well received and its second year of issue has been marked by a rearrangement of its previous sections and an addition of several others. The list of producers of artificial silk has, as might be expected, had to be extended and, in addition, particulars have been added of the types of silk made; the deniers produced in each type; the output, capital, and dividends of the concerns, as well as particulars of their representatives in this country. In a similar way other sections have been enhanced in value by the provision of further information. A chemical section has been added so that by reference to its pages the makers and suppliers of the chemicals used in the manufacture of artificial silk can be ascertained. In so far as this directory gives information of the foregoing character, it serves a most admirable purpose—it is surprising how often recourse has to be made to directories or would be made if such were available. But it cannot be said that there is any justification for articles such as those on "Fabrics without a Loom," and the "Construction and Installation of Artificial Silk Factories," in a directory such as this—their place is in the technical journals, surely. A bibliography of such articles, a glossary of terms, and a tabulation of comparative counts and yarn numbering systems would be well worth a place. It must be conceded that this directory is much required and has thus early shown every sign of fulfilling its functions admirably. —H.L.R.

American Society for Testing Materials: Proceedings of the Twenty-Eighth Annual Meeting. Volume xxv., Parts i. and ii. Published by the Society, Philadelphia, Pa., U.S.A. ($6.00 in paper, $8.00 in half-leather, per part).

These two volumes which, together, consist of over 1,400 pages, contain a very interesting and valuable record of the deliberations of this Society, which has now held no less than twenty-eight annual meetings. While dealing specifically with the subject—"The Promotion of Knowledge of Engineering Materials"—the President, Mr. F. M. Farmer, expressed views which can as well be applied to other materials. "Knowledge," he said, "can be promoted . . . in three ways—By developing and publishing information obtained through research carried on by the Society itself; by publishing information developed by its members individually, and by extending the usefulness of existing information. Through research the circle of knowledge is widened, while through education and publicity the contents of the circle are made available to a larger proportion of humanity and thus become more useful." It is gratifying to read that Mr. Farmer "placed special emphasis" on increasing the usefulness of the knowledge we already have. It cannot be too specially emphasised that the work of a scientific organisation embraces this particular aspect, and it may well be that other organisations have to some extent overlooked this point. Indeed, the whole of this address is of great value to any connected with the development and exercise of the true functions of a scientific organisation, and the American Society for Testing Materials are not only to be congratulated on such an address, but to be thanked for publishing it. The reports of the various Committees of the Society make interesting reading, while that of Committee D13 is especially to be noted here. Four new Sub-committees have been established and three

of them deal with fields of work new to Committee D13, viz. Rope and Cordage, Artificial Silks (Rayon), and Asbestos Textiles. Five, hitherto tentative standards, have been advanced to standard, and these will be dealt with in the Abstracts Section of this *Journal* at an early date. There can be little doubt that the work of this Committee justifies the claim of its Chairman—that a secure foundation for and awakened interest in testing textile fabrics and yarns has been brought about. H.L.R.

Reference to the "List of Publications added to the Library," pages P50–P51, will show that several books of interest have been received. Reviews of these have been held over for lack of space and will be included in subsequent issues.—EDITOR.

GENERAL ITEMS AND REPORTS

Philosophy in the Market Place*

On 26th February the President of this Society delivered an address on the above subject, in the course of which he pointed out that this country was faced in a more acute form than any other with the question of how to maintain a growing population. The crucial problem to be solved was—Could we to-day sell enough goods to pay for what we must import? There were two obvious remedies—(1) To increase the productivity of the soil; (2) to create a greater demand for our manufactured articles. Organised support was given by the State in the search for those remedies. For this end the Department for Scientific and Industrial Research had been formed, and some of the most original minds in the country acted as advisers to that body. The reluctance of the average manufacturing firm to employ a research staff was amply justified because it was extremely expensive. Organised industrial research could only be carried out successfully by great organisations. He used the term "research" in the sense which it acquired during the war. A research department was largely an intelligence department. It must examine all patents which appeared to have a bearing on industry, especially those taken out in foreign countries. If they were of technical merit, experiments should be made to discover something similar in order to meet foreign competition. Quick investigation of every foreign patent bearing on industry was the most important service that an intelligence department could give. It not only suggested analogous lines of research before the value of the invention was recognised by others, but also when the products made under the patent came on the market they could be identified, and it was well to have a "counter" ready. It must be remembered that when a chemical product was once well-established in the markets of the world, it would remain established until a new product offered by a competitor successfully attacked and perhaps replaced it. This kind of work could be called defensive research work. Industrially it was most important. It would be a great saving of effort if all this work could be centralised in the new laboratory at Teddington on behalf of the whole of our Chemical Industries. Speed was the essential thing. Most patents were worthless and could be reported so at once. It was useful even to know that a patent was worthless. Many firms would be glad to subscribe to such a scheme, which would be of direct service to the industrial community of chemists, and could not injure any British manufacturer. The regular publication of reports would demonstrate to the business world the extreme importance of following up the technical and scientific literature of the day. We should be able to develop, for the service of national industry, the wealth of scientific talent which this country fortunately possessed. Newer knowledge would lead to the development of new industries.

Burling and Mending

Mr. Sydney E. Illingworth, addressing the Huddersfield Textile Society on 8th February, on "Burling and Mending" (Mr. Ashley Mitchell presiding), said that whereas in the old days burling and mending was considered part of a weaver's duties, it had now reached a stage when not only had it become a separate

---

*From a report supplied by the Secretary, Manchester Literary and Philosophical Society.

department, but even a separate trade. Burling and mending was simply a barometer showing the efficiency or otherwise of weaving, and if a weaving shed was full of burlers and menders, it proved that it was not a properly efficient concern. With the old type of cloth a few ends or picks out made very little difference, as they could be covered up in milling or finishing, but in these days of finely-woven cloths, due to changing fashion and the desire for novelties, it was essential that pieces should be carefully gone over before being sent to the dyer and finisher, and great care had also to be used in the use of needles of correct fineness, proper tweezers or burling irons, and a knowledge of the proper type of cleaning material. The process did not end in the grey, or undyed state, as very often latent faults appeared after dyeing and finishing, such as foreign matter in the yarn, jute, and cotton bagging, &c., all of which had to be picked out, as well as weak threads which gave way in the dyeing or finishing processes. Many dyers kept their own staff of burlers and menders to deal with these faults, but in other cases the pieces had to be returned to the manufacturer to be remedied. There was no doubt that the burling and mending process had added tremendously to the cost of a cloth, and as, in his opinion, fully 50% of the faults found in a piece were due to faulty yarn, he suggested the advisability of burlers and menders being employed by spinners so as to ensure better yarns being supplied to the manufacturer. An improvement in the knowledge as to the ultimate use of a yarn would save a great deal of burling and mending. So far as manufacturers were concerned, much could be done to reduce faulty weaving by seeing that all yarns were properly tested and graded before being used for a particular type of cloth. The tuning of looms should also be carefully attended to, the looms set perfectly level, and greater use made of warp and weft stop motions—particularly the latter. A great saving would be the result. He had seen pieces containing as many as 85 broken picks which would have been reduced to eight or nine had a weft stop motion been employed. In fact, every method possible should be employed to reduce or get rid entirely of a process which now entailed the employment of one burler for every three weavers on two looms, and even in some cases three burlers to five weavers. With regard to the question as to whether burlers and menders should be paid on a piece-work or time rate basis, there was no doubt that burling and mending was a tedious occupation and trying for the eyesight, and on this account time rate was said to be the best method. But a great deal depended upon the class of worker, the type of work, and the conditions, particularly with regard to light, under which the work was being done. When on time rate, it was always a great difficulty to get pieces away to complete orders within the specified time. A better method, which was now in operation and worked quite well, was to combine the two methods in order to get a better production. For example, a piece would be calculated by the employer or forewoman in the department to take a certain number of hours for burling and mending, and the employee would be given a certain price—say a certain percentage above time rate—if the piece was finished within the stipulated time; any time taken beyond would be reckoned on the day rate. —M.

Cotton Yarn for the Bradford Trade

A lecture on "Features of Cotton Yarn for the Bradford Trade" was given before the Bradford Textile Society on Monday, 15th February, by Mr. S. B. L. Jacks (Messrs. R. Greg & Co. Ltd., South Reddish, Stockport). Mr. Sydney E. Illingworth, President of the Society, was in the chair and introduced the lecturer, who said that the Bradford trade required a strong, even yarn, regular in strength throughout and even in counts, clean and clear—one that could stand a considerable strain at all points. The presence of fluff was one of the chief causes of complaint made against cotton yarns to-day, and he regretted that the complaint was more than justified. Before the war they were accustomed to find plenty of hard, wiry cotton in Liverpool, but to-day—even in the best seasons—one had to look carefully round to find it, at least so far as American cottons went. The Egyptian crop was a rather different thing. Strength in yarns resulted from length or strength of staple, and what Egyptian had lost in strength it had certainly made up in length. Yet another serious cause for complaint in Bradford was what he had heard called "spotted" cotton. This was an inaccurate expression; he would rather term it "neppy" cotton. This was a fault to be found

in all cottons and was, he believed, primarily the result of picking the cotton too early before the seed had properly matured. Unless very numerous, these neps would go undetected in the yarn, and when the cotton was used as a warp to a worsted weft, no trace of them would be seen in the finished cloth and no damage was done. But when such a yarn was used for linings, with a cotton warp and weft, and the cloth dyed a dark solid colour, the effect was at once visible and spoilt the whole look of the fabric. A much more serious fault, at least from the point of view of the Bradford trade, was that which resulted from bad and dirty piecings. The spinner when piecing at one stage or another rubbed the two broken ends together with her fingers. If her fingers were dirty or if, in order to make the fibre stick more easily together, she licked her fingers first, a hard lump would be formed in the roving. This might never be drawn out in subsequent processes, or only partially so, and would appear in the finished yarn as a thick dirty end, sometimes extending for so much as three or four inches. Theoretically this fault should not appear where there was adequate supervision of the work, but there was no contending against human nature, and so long as the system of piece rates or payment by output existed, there would always be the tendency for the operative to turn out work as expeditiously as possible, rather than effectively. Another pernicious fault was that known as "single" or "double"—an end running very coarse or fine for some distance and then righting itself. This, in his opinion, was an almost unpardonable crime, but was finding its way all too often into yarn. For some time past he had been gradually coming to the conclusion that for doubled yarn the only satisfactory method of meeting the requirements of the Bradford trade was to produce a knotless yarn. This could easily be done by splicing the ends together, but this necessitated an extra process and a slightly increased production cost. The process consisted merely of untwisting the two ends to be joined together, then splicing the several threads together with a coating of beeswax and twisting them up again. The resulting splice was perfectly clean and imperceptible. This should prove a solution for many complaints in doubled yarns. In single yarns any universally-used system of splicing would be entirely out of the question and add too much to the cost of the yarn. In single yarns, indeed, splicing should not be necessary, a properly tied knot being so small as to be almost imperceptible. In conclusion, he pointed out how vitally important it was for the cotton merchant to understand the needs of the cotton spinner, and for the cotton spinner to understand the trade of the Bradford manufacturer.

THE JOURNAL OF THE

TEXTILE INSTITUTE

Vol. XVII APRIL 1926 No. 4

PROCEEDINGS

TEXTILE INSTITUTE EXHIBITION

KNITTED FABRICS AND NOVELTY YARNS FOR HOSIERY OR KNITTED FABRICS

A three-days' exhibition promoted by the Lancashire Section of the Textile Institute was held in the large hall at the Institute premises, Manchester, on the 18th, 19th, and 20th March. In promoting and organising the exhibition, the aim was to bring together exhibits of newest productions in reference to the particular branch of textile manufacture indicated. Invitations to exhibit were sent out to members of the Institute generally, and those members not directly interested were asked to bring the proposal before the notice of firms with which they might be connected. No charge was made for stand accommodation, and admission to the exhibition was free to ticket-holders or visitors presenting a trade card. The foremost idea associated with the effort was to afford facilities whereby progress taking place in one particular branch of textile manufacture might be readily visualised. The introduction of artificial silk and its utilisation in various ways in the knitting and hosiery industry were prominently expressed in the exhibits presented. Altogether, the presentation formed an interesting illustration of the rapidity with which developments have taken place in the utilisation of artificial silk or rayon. The exhibition was certainly well attended, particularly on the Friday and Saturday, 19th and 20th March, and on the latter date there was a special invitation to members of the British Association of Managers of Textile Works. In the evening a joint meeting of the Lancashire Section of the Textile Institute and the Association of Managers took place, when two short papers were read—one on "The Knitting of Artificial Silk or Rayon," by Mr. George H. Buckley, and the other on "Artificial Silk Sizing Problems, from the Machinists' Point of View," by Mr. W. B. Crompton. The following brief references to the exhibits provide a general idea as to the scope of the exhibition—

Messrs. John Bright & Bros. Ltd. (Carpet Department), Rochdale, showed special yarns printed in a series of shades showing variation of general tone by varying proportions of three different colours. Garments made from the printed yarn were also shown.

The British Celanese Limited arranged a most attractive stand, which displayed various special fabrics and garments made therefrom, and also Celanese hose and Celfect yarns.

Messrs. Copley, Marshall & Co. Ltd., Wildspur Mills, Newmill, Huddersfield, specialised in mercerised yarns, and their exhibit included a great variety of yarns of counts ranging from 2/420's to 2/1½'s, and in addition to two-fold there

were three-fold and many stranded yarns, the last being intended for hand knitting (jumpers) and embroidery purposes. A range of mercerised grandrelles (two-colour effects) was shown in colours fast to cross-dyeing. A special feature of the exhibit was the fineness of some of the yarn, which included 2/420's mercerised and dyed, as against the usual fine counts of 2/200's and 2/180's. Particular attention was drawn to the lustre of the yarns, and it is interesting to note that the members of this firm are the inventors of both the warp and hank mercerising machines which they use. The firm stresses the advantage of the water supply available for their concern as being an important factor in the maintenance of the lustre of mercerised yarns.

Messrs. R. Greg & Co. Ltd., South Reddish, Stockport, arranged their exhibits with a special showcase as a background, the case containing a range of fancy yarns, coloured and grey, in cotton and artificial silk, showing gimps, knops, slubs, and spirals. On each side of the case was a garment—one knitted from artificial silk and cotton, by hand, and the other machine knitted from an all-cotton solid-coloured gimp. Hanks of various styles of fancy yarns suitable for hosiery included coloured cotton gimps as fine as 10 hank. A specially interesting hank was an artificial silk floss yarn in the bleached state of a soft wool-like handle. A few cones were displayed, of which the most interesting was one of spun artificial silk (Vistra) and another of super-combed white cotton presented as a new speciality of the firm.

Messrs. Irwin & Co. Ltd., Manchester, presented several exhibits of their special knitted fabric, registered under the name of "Hopude." Both specimens of the fabric, plain and dyed, and garments and scarves formed an attractive collection.

Messrs. Ickringills (Silsden) Ltd., Silsden (Yorks), exhibited an excellent range of coloured fingering and double knitting yarns; fancy yarns for hand and machine knitting; fancy dyed yarns; and hosiery yarns of every-day requirement.

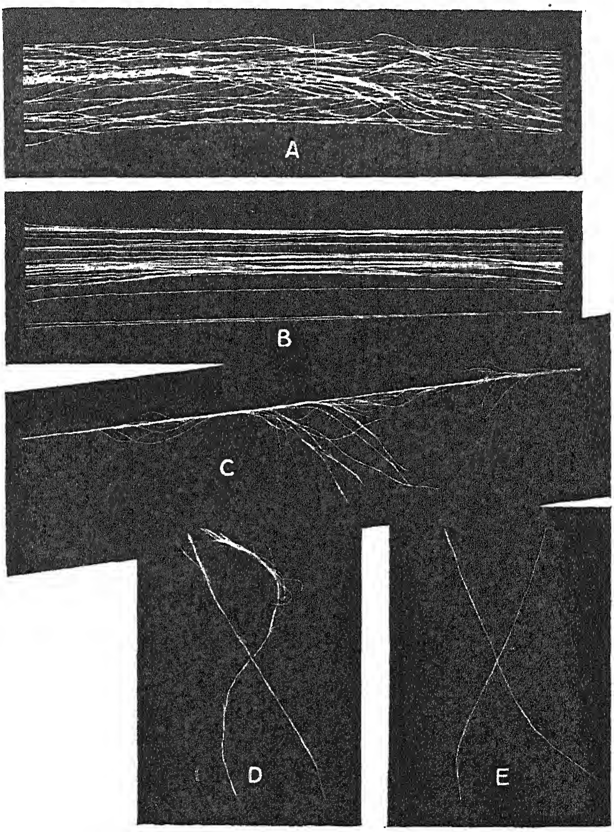
The Strines Printing Co. Ltd. (a branch of the Calico Printers' Association, Ltd.), contributed a fine selection of printed knitted fabrics which were artistically displayed on the platform of the hall. The exhibits included knitted cashmere woollens, plain knitted art silks, knitted art silk crêpes, and various specimens of fancy knitted goods. The printed knitted woollen cashmeres claimed particular attention both for their effectiveness and the compelling character of the designs.

Messrs. Burgess, Ledward & Co. Ltd., Wardley Mills, Walkden, near Manchester, contributed exhibits of cotton and artificial silk yarns as used in the knitting and hosiery trades. Among the cotton samples were cones of 8's-20's hosiery yarns dyed in ordinary and guaranteed fast colours for jerseys, 2-fold mercerised yarns (2/12's-2/20's) in ordinary and guaranteed colours, and 2/30's-2/100's mercerised and sericised, dyed in fast colours for hosiery tops &c. Samples of 2/30's-2/100's in grey sericised yarn were also shown. The artificial silk exhibit contained samples of viscose silk, natural and dyed in various shades, 150 and 300 denier, wound on bottle bobbin, cone, and cheese, for hosiery. Fancy artificial silk yarns were also on view, and included cotton and acetate-silk mixtures; 2-fold spun artificial silk, crêpe and bouclé twist jumper knitting yarns, in plain and rainbow shades, artificial silk marl yarns in two and three colours. Pieces of stockinette knitted from 250 denier and 300 denier viscose were also shown.

Messrs. J. & J. Hardman (1920) Ltd., Farnworth, near Bolton, provided an attractive exhibit of "Vistex" yarns—a mixture of viscose artificial silk and cotton. The exhibitors claim a particularly near approach in appearance and softness to spun silk and to pure silk when a low percentage of cotton is used. The marked lustre of artificial silk or rayon is absent, and fabric made from the yarn has a soft and pleasing texture, whilst it is claimed that it does not shrink. The yarn is stated to be suitable also for pile and cellular fabrics and suitings. It is supplied in counts from 60's down—in cop, cone, or cheese,

Messrs. J. E. Rowbottom & Co. Ltd., New Mills, Stockport, showed an excellent range of fancy yarns, including bouclé yarns for machine knitting in cotton, artificial silk, and in a mixture of both fibres. Onde yarns for a similar purpose from a mixture of wool and cotton yarns were shown, as well as sample cloths showing cross-dyeing effects with these yarns. In addition marl effects in dyed and printed mercerised cotton yarn doubled with white artificial silk, and mixture yarns in wool and artificial silk, were displayed in varieties of count, as well as both in hanks and on cones.

Messrs. Samuel Walker & Sons Ltd., Radcliffe, near Manchester, displayed photographs of a patent sizing machine for the sizing of artificial silk warps, together with samples of warps sized on the machine and illustrating the quality produced in comparison with hank-sized warps. In the case of the machine-sized warps, the filaments were shown closely bound together, whereas in hank-sized warps the filaments sometimes appeared loose and separated. The machine sizes, from beam to beam, a warp consisting of 54 ends only, and up to the usual maximum, according to denier. The diagram herewith is self-explanatory.



A—Portion of a hank showing outstanding filaments.

B—Portion of a machine sized warp perfectly free from outstanding filaments.

C—A partly broken hank-sized yarn; the filaments break one by one.

D—A completely broken yarn of the same type, showing how the whole thread comes asunder.

E—A completely broken machine-sized yarn.

The British Thomson-Houston Co. Ltd., Manchester, demonstrated the firm's "Trutint" electric lighting units, together with "Mazdalux" reflectors for mill lighting, and other specialities in electrical equipment. The firm generously provided special lighting, facilitating the displays on several of the stands.

The Mons Mill (1919) Ltd., Todmorden, had a special exhibit in the centre of the hall—an elaborately built stand containing American yarns in various forms of make-up, and illustrating process stages of manufacture.

Messrs. Edward Hall & Bro. Ltd., Botany Bleach Works, Whaley Bridge, near Stockport, showed samples of bleached and tinted raw cotton in various stages and samples of artificial silk waste and cotton mixtures.

Messrs. Edmund Whittaker & Sons Ltd., Oldham, showed a big variety of fancy-effect yarns, both of cotton, and of mixtures of cotton and viscose and of cotton and Celanese. Garments of knitted fabrics and hose served to illustrate the effect of the employment of the yarns in manufacture.

The Lispro Yarn Co. Ltd., Rochdale, exhibited a number of yarns both in grey, processed, and dyed state, and of particular interest were the examples of dyed material subsequent to the special process in comparison with dyeing after normal treatment.

Lancashire Section

Joint Meeting with the British Association of Managers of Textile Works, held at the Institute, 20th March 1926, Mr. Percy Bean presiding.

The joint meeting was held in connection with the exhibition of Knitted Fabrics and Novelty Yarns for Hosiery and Knitted Fabrics. Two papers were read, and the Chairman called upon Mr. George H. Buckley to read his paper first.

THE KNITTING OF ARTIFICIAL SILK OR RAYON

Mr. Buckley said that there was now no reason to doubt that artificial silk was firmly established in the manufacture of textiles, and it was estimated that 40 per cent. of the weight produced was converted into knitted fabric in one form or another. Knitted fabrics could be placed into two classes—warp fabrics and weft fabrics. To illustrate the former, the lecturer showed a sketch of the Denbigh fabric. The knitting of warp fabrics, he said, was usually carried out on straight bar machines, various types of which might have one or two needle bars, and one or more guide bars, according to the particular type of fabric required Another sketch he showed was of a plain weft fabric, and this illustrated the bending action to which the weft thread was subjected.

Mr. Buckley said that artificial silk was a smooth fibre resembling a semi-transparent glass rod, and the least irregularity in the size or shape of the loop was easily detected. Knitted fabric was a uni-thread structure, and therefore clearly disclosed the difference in denier or lack of uniformity in the yarn. The lecturer described the formation of a course of loops on the hand frame, which, he said, still produced the finest class of goods. He then referred to Cotton's patent frame, mentioning the numerous automatic attachments that had been added for the production of fancy goods. The manufacture of fine knitted fabrics on the circular system had been accomplished on the French or German bearded needle machine for many years. Mr. Buckley stated that in the manufacture of medium and coarse gauge fabrics, latch needles were generally used, and proceeded to describe this particular needle and its action. Many operations in needle making were dependent on the human element, and variations would occur which were a source of trouble to the knitter. These created faults in the fabric which were easily observed, and therefore particular care should be exercised in the selection of the needle. The lecturer emphasised the importance of keeping a uniform tension, which he said should be as low as possible consistent with the amount required to prevent the collapse of the cone. Winding

of artificial silk had to be very carefully carried out. A very efficient arrangement fixed to some winding machines was one which would stop the spindle if the artificial silk from the hank became entangled or obstructed by an improperly tied knot. It was essential that faults which occurred in the yarn should be detected in the winding department, as it was a costly business to find them on the knitting machine. The lecturer concluded by stating that it was advisable to knit artificial silk immediately after winding, as atmospheric changes very materially affected the manner in which it unwound.

The Chairman said that the paper rather appeared to him to differentiate between the sexes. When women used to do all the knitting work, they did it by hand, as they still did crocheting. When men began to take up knitting, however, they invented machines to save themselves the trouble of manual labour. He then asked Mr. W. B. Crompton to read the second paper.

ARTIFICIAL SILK SIZING PROBLEMS FROM A MACHINIST'S POINT OF VIEW

Mr. Crompton said it could easily be seen by anyone handling artificial silk supplied by the spinners of the material, that the thread was composed of a number of filaments laid parallel to each other and with scarcely any twist in the yarn to keep the filaments together, which was not the case with cotton and other textile yarns. For a time artificial silk was almost entirely used as weft, and its suitability for warp was first obtained by making a two-fold thread with a fair amount of twist. Twisting artificial silk either in the single yarn or in the twofold provided a stronger yarn more resistant to wear at the cost of a corresponding sacrifice of the lustre, and therefore it was determined that to obtain the full lustre in the warp some method must be found of so preparing the more open yarn that fibres were protected from breakage in the process of weaving, and that they might spread out and give both cover and lustre in the finished fabric. The problem was rendered more difficult by the characteristic features of the ordinary artificial silk thread, viz., that it weakens when in a moist condition, and also that it elongates considerably under the same condition, though it contracts and strengthens as it dries.

In dealing with sizing, the lecturer said that many of the ordinary methods of sizing had been attempted, among which were cylinder and hot-air methods of slashing cotton warps. It was natural that these methods would prove unsatisfactory because of the long stretch while in its wet state, which caused strain in the yarn when in its weakest condition. Yarn sized under such conditions was bound to suffer in strength even if the working condition and sizing results could be considered satisfactory. Hank sizing had been tried, and in this connection many experiments had been carried out. Hank sizing left the threads in a suitable condition for winding, but Mr. Crompton was of opinion that so far this method had not proved satisfactory for weaving purposes. In his opinion artificial silk yarn to be suitable for weaving should be rolled into the size in such a manner that the thread was left with no outstanding fibre or filament, and that when a dry thread was taken between the finger and thumb of both hands and an attempt made to twist and untwist it, the whole yarn should simply turn and hold together, and none of the individual filaments become separated. In order to obtain these conditions, a specially designed machine was obviously needed; at the same time the machine should be as easy of manipulation and of access to the yarn at every point as it was possible to make it. Mr. Crompton then showed photographs of a machine made by Messrs. Samuel Walker & Sons, of Radcliffe, in which he thought these objects were successfully achieved. He went on to describe the machine, and in what manner it achieved the desired ends in sizing artificial silk yarn. A machine of this type, Mr. Crompton said, was very adaptable for different classes of work, and by the adoption of a slight traverse motion the silk could be laid perfectly even on the roller

with very few threads in the warp, as few as 54 having been successfully treated. By opening out the yarn in a front stationary reed a group of bobbins could be filled for use in Dhootie borders, or by spacing in the reed, unevenly spaced stripes could be built up on the weaver's roller successfully, provided each was equally dented in the reed, and paper used freely to bind the silk stripes together.

Discussion

The Chairman said that the two papers had been extremely interesting. One of the points raised in Mr. Crompton's paper showed how things that were detrimental in certain cases became of advantage in others. Many of those present would know that one of the troubles in tape sizing, in dealing with coloured borders, was the dreadful trouble of twirling. In this case it seemed that the small degree of twirling set up was of very great service in the sizing and subsequent weaving of artificial silk. It was probable there were still a great many difficulties to be overcome in the sizing of artificial silk. Elongation during sizing and stretching in the loom during weaving were points requiring very careful consideration by all people concerned with artificial silks.

Mr. Buckley, speaking with reference to the effect of moisture on rayon, stated that atmospheric changes when the rayon was under tension, i.e., when it was being wound on the bobbin, very materially affected the manner in which it unwound. For this reason it had been found advisable to knit rayon as soon as possible after winding and not let it stand.

Mr. Farrow said he had seen the machine described in actual running. The conditions of drying were very different from those of tape sizing. The contact with the hot metal was very much shorter and much less efficient. It would be interesting therefore to know at what rate the machine was run, also the strength of the size and so on. Could they be told at what speed the yarn was run on to the beam ?

Mr. Crompton said that it would vary. If there was a fine denier, which would dry quickly, and the result depended partly on the drying efficiency of the machine, the speed would be, approximately, about 5-7 yards per minute.

Mr. G. Dougill inquired whether Mr. Buckley had any preference in knitting yarns in having the twist in the yarn twist way or weft way ?

Mr. Buckley replied that, as far as he knew, in the knitting of fabric no change was required to be made in the direction of the twist. He thought, generally speaking, that was only necessary in the making of lace, which was, of course, a twist fabric and not a loop fabric.

Mr. Dewes stated that to the circular hose machine, which was so much used in Leicester, there used to be fitted a small bottle which contained a little wick and some oil. The thread passed over the wick and got a very intimate coating of oil. The knitters felt the want of something of the kind, and while some of them struggled along with this particular method others abandoned it. Could Mr. Buckley say, from his own experience of knitting artificial silk yarns, whether such a method was advantageous ?

Mr. Buckley replied that there was no question about it—that the lubrication ought to take place before the yarn was put on the knitting machine. Woollen yarns were soaked and centrifuge-extracted, in which case, of course, "lather" was used; but any tension which was applied on the knitting machine by lubricating was to be avoided as far as possible. The less tension, or rather the more control of tension, that could be exercised over the yarn from the bobbin to the needle was certainly best on the knitting machine. Rayon was lubricated in hank form and wound. It was sometimes necessary to increase the lubrication. This, of course, had to be done on the machine, but as far as possible it should be avoided.

Mr. A. B. Shearer thought that the last question put and its answer also had relationship to sizing for weaving. He was satisfied that the definition given by Mr. Crompton of satisfactory sizing was not quite correct, because it

was fairly obvious that if the only test was the clinging together of the individual filaments that sizing the warp with fish glue would come up to the definition of being an efficient size, which, of course, was obviously incorrect. What the last question really implied was the emulsifying or the providing of some sort of lubricant used for the yarn, whether it was going through a knitting machine or going through a loom. Personally, he held the opinion that an efficient size for weaving had to be at least as much a lubricant as it had to be an agglutinant for the purpose of holding the fibres together.

A member inquired whether the machine mentioned by Mr. Crompton could be seen under working conditions. Mr. Crompton had spoken about sizing 54 ends on the machine from beam to beam, while at the same time the ends of the yarn when wet were very weak indeed. Fifty-four ends did not seem strong enough to pull the beam round.

Mr. Crompton replied that there was an arrangement whereby the machine could be inspected by anyone who was inclined to purchase one. It had been working successfully for some time. With regard to the 54 ends and the weakness alluded to, he had pointed out that the yarn was in the size for so short a distance that there was very little risk of elongation. The yarn was on the machine, and practically drying, before there was any weakening effect such as would be expected in the ordinary way. Yarn had been sized with 54 ends, and evidently it had been woven satisfactorily because there had been no complaints. The beam could be very lightly adjusted.

Mr. S. Watson proposed a vote of thanks to the authors of the two papers, and to the chairman for presiding. He was very much struck with the distinct advancement which had been made in knitted fabrics. As cotton yarns were used extensively in knitted fabrics there should be a corresponding benefit to Lancashire. Judging from what they had seen at the Exhibition an effort would certainly have to be made to cope with the ever growing demand for knitted fabrics. It was up to Lancashire to produce the yarn for them, and consolidate another phase of the cotton industry. He wondered if it would be possible to use a printed cotton yarn and make a floral effect in the knitted fabric? He thought it would be. He had given the matter considerable thought, and believed it was possible that printed cotton yarns could be employed in knitted fabrics, and picked up by some Jacquard mechanism which would combine a knitted effect with a floral design. It would be a step forward, and, of course, being a step forward would go against weaving; but at the same time it would perhaps increase the further demand for cotton yarns. He had been very much struck, when examining some cloth the previous day, by a mixture of cotton and viscose and also of Vistra. The suppleness of the cloth was quite remarkable, and it was not at all a matter of surprise to find there was a large demand for such a fabric. The amount of elasticity and retentive elasticity was remarkable. Of course this was owing to the foundation of cotton, and the Vistra or viscose being spun along with the cotton. The metallic effect which was apparent in all artificial silks was neutralised to some extent. Artificial silk, when spun with cotton, created air pockets in the thread, the consequence being a better article of clothing as regards warmth, even than with artificial silk alone, and also a better wearing surface. It would be disastrous for the thread to roll in cotton sizing; but he could see that if by some mechanism the rounding off of the thread in cotton yarn could be secured it would be of distinct advantage, because there would be a clearer thread and a clearer weave.

Mr. A. Mitchell Bell seconded the vote of thanks. He had listened to both papers with keen interest, the result being that he had not quite such hard feelings as he might have had some time ago. Early on in his career it was his lot to produce certain types of atrakhan fabrics. His firm had got going nicely, and had opened a market for the fabrics, when one of their competitors came along with a type of astrakhan fabric produced upon the knitting frame which

completely knocked out his firm in price. In order to cope with this competition, a number of knitting machines were installed for the purpose of producing a similar type of fabric and regaining the market. At that time he was under the impression that the knitting machine would not be able to produce a wide variety of designs. It was now quite evident that there was a great scope for such machines, and that there were many possibilities in the direction of new designs. Had Mr. Buckley had any trouble with cracked threads, because in the cloth trade, in introducing artificial silk as stripes, and so on, it was found that in the finishing of the fabrics a number of the threads cracked? When there were a number of cracked threads the customers were not slow in complaining about them.

The vote of thanks was heartily accorded.

London Section

Discussion Meeting in the Institute's Rooms, 38 Bloomsbury Square, W.C.1., 3rd March 1926, Capt. S. E. J. Brady in the chair.

SOME PROBLEMS OF THE WORSTED TRADE

Capt. Brady introduced the lecturer, Mr. T. Bray, who said—The problems which beset manufacturers of worsteds are perhaps more numerous than in other sections of the textile trade, because of the many processes that are necessary before the yarn can be woven into cloth. The tendency of the past generation or two has been all for specialisation in the various processes; thus, instead of manufacturers taking in the raw wool and turning out the woven piece, we have separate concerns engaged on each process. The spinner buys his top from the comber (who to-day has reached a very fine art in blending his tops) and draws and spins it into yarn. The drawing process through which the fibre passes actually includes some nine progressive stages. The roving is drawn out by passing between two sets of rollers, the front pair going round quicker than the back, until it is drawn sufficiently for the spinning thread. The yarn is then spun to the required counts, this being regulated by the speed of the rollers; the quicker the speed, the thicker the counts. The spinner has many pitfalls, one being that quality deteriorates if he tries to get too fine in the counts. Sometimes the blending of the top has not been quite what he expected, and it is only when he gets to the spinning frame that the real test comes. A bad spin, that is, constant breaking of threads, &c., is a difficulty the weaver oftentime has to contend with. Specialisation has its advantages, not only for the manufacturer, but for the trade in general, as it gives the manufacturer more freedom in choice, and, again, the fruits of research and experience gained from the study of each separate process can be fully utilised. There is every desire on the part of all sections to turn out as perfect an article as possible, though it is much easier to weave a well-balanced 18 oz. merino or botany from a 70 top, 3 by 3 twill, than from a low cross-bred or some of the fabrics for ladies' wear. This problem of turning out a well-woven piece is sometimes a source of great anxiety to the operative. Weaving is a much more highly skilled operation than many seem to believe. The weaver and overlooker together often have to overcome many difficulties the seeds of which have been unwittingly sown in previous processes. Some distributors seem to have the idea that piece goods can be turned out with the exactitude of cigarettes or pins, simply because machinery is used for each process. Let us for a moment go into detail. As you are aware, raw material for the worsted trade includes not only a big variety of wools from the sheep, but also alpaca and mohair. For some time the British Wool Association has been trying to press home to the sheep farmer, particularly in the Colonies, the need for careful packing of wool. Any kind of common canvas used to be considered good enough for packing, and wool, being very adhesive, attracted loose vegetable fibres and burrs from the

canvas, and these do not come out completely in spite of all the processes to which the wool is afterwards subjected. They are often not seen until the pieces are dyed and finished. The result is that the cost of burling pieces is a very serious charge to manufacturers, varying often from 2d. to 6d. per yard. There are signs that the work of the Association is bearing some fruit, and I believe some schemes are already afoot to remedy this defect. Of course some wools are by nature burry, and on that account must be carbonised, which seems to take a good deal of the life out of wool. It must always be remembered that wool is an animal fibre, which probably accounts for the variety in quality and handle. Another very important process which, if not carefully carried out, has a bad effect on the pieces, is that of wool-washing, and here scientific research and experience have played, and are playing, a very important part. Care has to be taken to use the right soaps, and that water is at the proper temperature. Not only has the grease to be extracted, but the residuals must be cleared as well, or the remedy would be worse than the disease. This work is done by the comber, who after sorting the wool into qualities, passes it on to the wash bowls, after which it is dried and prepared for combing. It is in the combing where blends of qualities are made, and it is somewhat difficult to fix a standard. The safest way is for the manufacturer to fix his standard from his experience of the finished article. It is generally assumed that qualities are fixed according to spinning properties, but to-day that is not so. When a spinner buys what is known as a 60's top, that is the lowest merino, one might think he could spin it to 60's, but 2/48's would in all probability be the limit. To spin to 60's, the spinner must get a good 70's top. The lecturer here defined the bases of the worsted, woollen, and cotton counts. He then said—Blending from various qualities of merino has reached a very fine art, so much so that in fine counts it is easy to estimate a quality, but in thick counts it is much more difficult to place. This is achieved mainly by constant experience of handling the cloth. I have mentioned the processes which occur before the yarn is ready for the weaver, because the test for good preliminary work is in the looms and the finished piece. Taking into account the number of hands through which the material passes in the worsted process, it is astonishing that the degree of excellence is so high. This has only been brought about by the co-operation of all engaged—comber, spinner, and weaver—all of whom must be very highly skilled. I have met distributors who had little knowledge of these matters, and it is most difficult to make them understand. On the other hand, the distributor who has taken the trouble to learn something of the textile industry is usually not only amenable to reason, but able and willing to co-operate with the manufacturer in matters affecting his requirements. I am afraid that so far as textile shipping is concerned London is not so much the distributing centre as formerly, simply because the shipping houses of Bradford and Manchester are in the main staffed by men who have been cradled in the trade. I can understand this to some extent as many London shipping houses do not confine themselves to textiles, but export many other commodities. It is not to be expected that they will be conversant with everything, but I submit that many shipping house buyers could, with profit to themselves, co-operate more with the manufacturers than they do. For instance, the distributor could help very materially to reduce costs of production by studying the needs of the particular market in which he is interested, so that he knows what is wanted. At present he asks for patterns without giving much indication as to what is required, with the result that innumerable patterns are wasted, all of which goes down to expenses of production. This reminds me of the important question of costing, which demands careful attention on the part of the cloth manufacturer. No rule-of-thumb method will do here; he must know exactly what a particular piece costs to make. Of course all sections must face the same problem, but the weaver especially, when buying his yarn from the spinner,

has many things to watch, as, for example, weavers' wages, and actual counts of yarn supplied as compared with those ordered. Overhead charges to-day when compared with pre-war charges are evidently one of the important causes of higher prices. Local rates have advanced very considerably, and so has every commodity used by the manufacturer. If he can keep his machinery running and his production up he is all right, but if he cannot keep all his machinery going, his profit per piece is seriously reduced, often to vanishing point. All good manufacturers desire to keep the wage level as high as possible, for a country's wealth is measured by the spending power of the people. Reduction in costs can only come about by careful management and the elimination of waste by workpeople, apart, of course, from the question of reduction of rates and taxes. The comparative efficiency of the workman is an important factor in calculating the cost of weaving, more so than in any other branch. It is safe to say that as a rule we do not get more than an average 60% of the possible full production of the loom. A manufacturer must know his output before he knows his cost accurately; the better the piece weaver, the less stopping of the loom and the greater the production. A curious point with regard to figures of output in weaving is that greater production is often reached at certain periods, especially when no artificial light is required. The two or three weeks preceding a holiday are also remarkable in this respect; weavers, as you know, get paid according to their production. Wools vary in length from $1\frac{1}{2}$ in. to 17 in. and in fineness from 1/200th to 1/2,000th part of an inch, and these variations demand different treatment. Apart from the Continental system, there is not a very wide choice of machines. The Continental spinners have studied the manufacture of worsted yarns from short wools very thoroughly and with profit. Since the war we, too, have made progress in this direction. As I have already pointed out, the shrinking properties of wool vary very considerably, not only according to quality but according to the build of the cloth. A manufacturer, when he makes a new cloth (usually a pattern), must keep a record of the width in loom, the finished width, and length. Some one has said that 75% of accidents are traceable to human errors; it would be safe to say that this is very true of textile manufacture. The cost of the suit you are wearing is all labour, after the initial cost of the raw wool, soaps, oils, dyes, &c., has been met. Tracing mistakes and faults in pieces is very interesting, for even experts can be led astray. I knew one case where a piece appeared to be "warp-stripey," and we thought two different runs had been mixed in the warping. The dyer took back these pieces to remove crimps which were in the cloth, and when they were returned we found the striping had vanished, much to the satisfaction of the manufacturers. Nobody seemed to know what the trouble had been. Common weaving faults are as a rule traceable, but if a piece weaves badly we cannot always blame the weaver; one must go further back. A fault may have its root in the combing, the drawing, or the spinning, and if in the combing the spinning will aggravate rather than improve the weakness. From a microscopical standpoint the first perfect piece has yet to be made, but I am certain that the standard of weaving was never higher than it is to-day. The art of fault-finding has also reached a very high level, and sometimes customers set an impossible standard. There is an important point I want to raise concerning the quality of worsteds. As you are aware there is merino *and* merino, and the same remark applies to cross-bred. There is nothing easier than to lower quality in an 18 oz. botany. The distributor or merchant thinking a quotation dear, gets cheaper patterns from another source, and may select one. This may be repeated from yet a third source, and, while there may be not much difference between the first and second, or the second and third patterns, the difference between the first and the third would be obvious to the merest novice. If patterns from animal fibres are kept carefully between boards, they improve, and this very often creates a serious problem for the manufacturer. It is sometimes very risky to take orders with old patterns as standards, as nothing but

time will give the soft mellow handle of an old pattern. When orders come along with the old pattern as standard, we have been unable to get quite what was required, in spite of the finisher's art. Particularly is this the case with mohair and alpaca. The time-factor is very important when dealing with mohairs. In two yarns spun from the same top, one in which care had been taken to keep the roving for about three weeks before spinning, and the other which had been rushed through without allowing the roving to stand, there would be a great deal of difference; that which had been rushed through would be uneven, and look in places as if ready to burst. Curious though it may seem mohair tops improve with keeping; the best results will not be obtained unless plenty of time is taken over the processes. This is very difficult when a manufacturer is given a limited time for delivery in order to catch the season's trade; I mention this in reply to much criticism that has been levelled at the worsted manufacturer for his delay in delivery. Research work on mohair is being conducted in order to find some remedy for this delay, so that the spinner can go straight ahead without wasting so much time. The anxiety to keep up to date is very real, and experiments are constantly being made in top building and designing. The latter is a source of expense little realised by the distributor, for scope is almost unlimited in both the coating and the dress trade. Unfortunately the initiative usually has to come from the manufacturer, the exception being when the merchant has taken the trouble to understand something of textiles; a point I have already raised. As a rule, shipping houses merely ask for patterns without giving any suggestions of modifications for particular markets. The average manufacturer is not behind the times, but many distributors still rely on the old method, and take in all the patterns a manufacturer can send without thinking of the cost. Those who are progressive enough to know their own market requirements and who have initiative are doing a better trade. Our manufacturers of dress fabrics have been accused of not keeping up to date with Continental makers, and of not making full use of the dry spun yarn from short wool. It must be remembered that cap spinning is most suitable for the production of yarns for worsted coatings and the better grades of ladies' costume cloths. Our spinners have held the field in this particular class of spinning, and spinners on the Continent have adopted dry spinning because they cannot compete with our cap spinning. This was the only way in which they could come into the market with lightweight dress fabrics. One of the features of dry spun yarn was that the dyer could get more delicate shades than with cap spun, which is spun in oil. To-day very delicate shades can be produced with cap spun yarns quite equal to any of the dry spun yarns. It is admitted that fine single mule-spun yarns are cheaper than the equivalent counts in two-fold cap spun yarns, but advances have been made in developing the mule-spinning side in England in spite of the fact that in pre-war days some of the spinners who put down such machinery had their fingers burnt severely. However, such progress has been made by the co-operation of spinners with dyers that many dress fabrics turned out in the Bradford area to-day are equal to, if not better than, the best productions of the Continent. There is much variation in the affinity for dyestuffs among the many different qualities of wool, and after dyeing several pieces together for one shade, it may be found that they vary considerably. We find it very difficult to convince the distributor that it is not always possible to repeat exact shades. We can get approximately near, but we cannot always match so that no difference whatever is discernible. I have only touched the fringe of many topics of this industry, each branch of which is seething with problems. Those of you who were fortunate to hear the lecture by Mr. Fry on "The Production of Design in Fabrics," a subject I have left severely alone, will remember that he could not get through half he wished to say in the time available. I have tried to give a general outline which, I hope,

has been of some interest, and I hope that some parts at least may be useful to you; if so, I am more than compensated for taking up your time.

After a very short discussion, the Chairman moved a vote of thanks to the lecturer, which was carried with acclamation.

NOTES AND NOTICES

Diplomas of the Textile Institute

First Instalment of Awards of Fellowships and Associateships

The first instalment of awards of Fellowships and Associateships of the Institute, under the scheme indicated in the Royal Charter of Incorporation, and under the conditions governed by the bye-laws, was presented at the annual general meeting of the Institute on Wednesday, 21st April. The first Fellowship was presented to the retiring President (Mr. John Emsley, J.P., of Bradford) at a special function at Bradord on the 25th January last, whilst the second Fellowship was separately awarded to Mr. J. H. Lester, M.Sc. (Chairman of the Selection Committee) at the annual meeting already referred to.

The full list of Members of the Institute who have now been elected Fellows and Associates is as follows—

FELLOWS

JOHN EMSLEY (Bradford), President of Institute, 1922-3 to 1925-6, First Fellow.

JOSEPH HENRY LESTER (Monton, Eccles, near Manchester), first Chairman of Selection (Diplomas) Committee, Second Fellow.

ADAMSON, John Evan (Accrington).
ANDREWS, Michael Corbet (Belfast).
ATKINSON, Ellis (Bradford).
BAILEY, Reginald Greenwood (Bradford).
BAILEY, Walter (Ashton-under-Lyne).
BARKER, Aldred Farrer (Leeds).
BARRETT, Frank Leslie (Davenport, Cheshire).
BARWICK, Fred Wilkinson (Manchester).
BELL, Arthur Mitchell (Halifax).
BINGHAM, Thomas Ernest (Ashton-on-Mersey, near Manchester).
BINNS, Henry (Bradford).
BOOTH, John (Glossop).
BOOTHMAN, William Thomas (Duxbury, near Chorley, and Bolton).
BRADBURY, Fred (Belfast).
BRADY, Sydney Edward Joseph (London).
BRIERLEY, Sam (Huddersfield).
CHADWICK, Fletcher (Rochdale).
CHAPMAN, Albert Martin (Burley-in-Wharfedale, near Leeds).
CROMPTON, John (Lytham and Manchester).
CROMPTON, William Bickerton (Walkden, near Manchester).
DAWSON, James Henry (Brierfield, near Burnley).
DENISON, Joseph Richard (Bradford).
DUMVILLE, Joseph (Bradford).
ENGLISH, Walter (Buenos Ayres, Argentine).
FOULDS, Robinson Percy (Manchester).
FOULDS, Thomas (Colne, Lancs.).
FOX, Thomas Alfred (Gomersal, near Leeds).
FRY, Ernest Bickersteth (London).
GARNETT, George (Bradford).
GARRETT, Albert Edward (London).
GREG, Henry Philips (Styal, near Manchester).
HALL, Oscar Standring (Bury, Lancs.).
HEAPS, William (Bolton).
HENDERSON, Sir William (Dundee).
HEYLIN, Henry Brougham (Tilehurst-on-Thames, Reading).
HILL, Harold (Bolton).
HOLDSWORTH, Ernest Thornton (Bradford).
HOLLINGS, Samuel Banks (Bradford).
HOPKINSON, Frank (Bradford).
HOWARD, John (East Sheen, London).
JAFFÉ, William Edward Bertold (London).
KERSHAW, Samuel (Bradford).
KIRK, William Watson (Colne, Lancs.).
McCONNEL, Frederic Robert (Manchester).
MASON, Arthur (Macclesfield).
MIDGLEY, Eber (Bradford).
MILLS, Lord John (Surbiton, Surrey).
MOORES, George (Chorlton-cum-Hardy, Manchester).
NASMITH, Frank (Manchester).
NISBET, Harry (West Didsbury, Manchester).
PENNINGTON, John W. (Burnley).
PERL, Alfred George (Vienna, Austria).
PORTER, Frederic Charles (Lytham).
PRIESTLEY, Edford (Farsley, near Leeds).
READ, John (Monton, Eccles, near Manchester).
ROBINSON, John (Denholme, near Bradford).

ROBINSON, Thomas Fletcher (Pendleton, near Manchester).
SAVILLE, Arthur (Bradford).
SCOTT-TAGGART, William (Bolton).
SHANNON, Francis John Wesley (Belfast).
SHAW, Arthur (Macclesfield).
SHEARER, Andrew Blair (Kersal, Manchester).
STAFFORD, George Harold (Hyde, Cheshire).
TAYLOR, Samuel (Littleborough).
WARNER, Sir Frank (Mottingham, London).
WATSON, Samuel (Hyde, near Manchester).
WATSON, William (Glasgow).
WHARTON, Thomas Richard (Wilmslow, Cheshire).
WIGGLESWORTH, Edwin (London).
WOODHOUSE, Thomas (Wormit, Fife).
WRIGHT, Frank (Bolton).

ASSOCIATES

BARKER, George (Ben Rhydding, Yorks.).
BARR, Joseph (Nottingham).
BEATTY, George Rooston (Coalisland, Co. Tyrone).
BRAND, Alexander (Arbroath).
BURROWS, Stanley Lees (Hawick).
CAIRNS, William Hewitson (Bradford).
ESSAM, John Maltby (Manchester).
GEARY, Andrew Roy (Dunfermline).
GREENWOOD, Robert Stansfield (Bradford).
HALSTEAD, Frank (Burnley).
HARDMAN, Alfred (London).
HAWORTH, Frederic Wilson (Nelson).
LEWIS, Albert Easton (Manchester).
MICHIE, John Livingston (Hawick).
MILNES, Alfred Hallett (Timperley, Cheshire).
MORTON, William Ernest (Didsbury, Manchester).
NUTTER, Handel (Nelson).
ODDIE, Edward (Burnley).
OLIVER, James Henderson (Hawick).
OVERSBY, Reginald Greenwood (Bradford).
RAYNER, Slater (Bradford).
REIDY, John William (Manchester).
RUSHTON, George Albert (London).
SCHOLFIELD, John Albert (Todmorden).
SHACKLETON, William Taylor (Westhoughton, near Bolton).
SHARP, Frederick Irvin (Glossop).
TRUESDALE, Reginald (Birmingham).
WILKINSON, James Arthur (Burnley).
WRIGHT, William Henry (Swinton, Manchester).

Annual Conference at Buxton

Arrangements are proceeding in regard to the next Annual Conference of the Institute, which is to take place at Buxton during Whit-week, and members generally are asked to make every endeavour to attend. It is expected that the proceedings will commence on the Wednesday evening of 26th May by a social assembly. On the morning of the 27th May the Conference will open at the Town Hall, and a prominent feature will be the delivery of the Mather Lecture by Sir William H. Bragg, K.B.E. The afternoon and evening will probably be left free to members to pursue engagements according to inclination, and in this connection it is hoped that special facilities for golf may be available. On Friday, 28th May, the Conference will be resumed (morning session), and in the afternoon it is proposed to organise a drive—probably to Macclesfield—where it is hoped to be able to inspect one or two textile works. It is fully expected that many members may decide to spend their Whitsun holiday at Buxton. The railway companies have declined to grant special railway fare facilities, but the general holiday and tourist fare arrangements of the companies can be taken advantage of, whilst many members will doubtless travel by road. Hotel and other accommodation for visitors is quite extensive at Buxton, and particulars will be in the hands of members by the end of April.

London Section Activities

The Annual Section Meeting of the London Section was held in the Institute's London Rooms, 38 Bloomsbury Square, W.C., on Thursday, 15th April, at 6.0 p.m. Mr. Edwin Wigglesworth, the retiring chairman, in a *resumé* of the year's work, mentioned that at length the Committee, with the help of some useful criticism from Mr. J. H. Lester, had formulated a particular policy for the London Section, subservient to the general policy of the Institute, and that it was the

intention of the London Committee to give wide publicity to this policy. Arising out of decisions at the Section meeting, a visit is being arranged to inspect the hosiery works of Messrs. Dix, Watson & Co. Ltd., of Alperton, Middlesex, some time early in May. It is hoped to arrange a similar visit to a weaving factory later in the summer. Arrangements have also been made for an Exhibition of Fabrics, woven under Bradford Textile Society's Prize Scheme at Bradford Technical College, to take place in the Institute's London Rooms on Wednesday and Thursday, 12th and 13th May 1926. Representatives of London textile distributing houses are to be invited to inspect these fabrics and offer criticism.

Annual General Meeting—Council Election

Our report of this event (21st April), covering the election of President (Mr. William Howarth, J.P.) in succession to Mr. John Emsley, J.P., the election of Vice-Presidents, and the result of the ballot for election to ten vacancies on the Council, cannot appear until next issue owing to the narrow margin of time available for printing. The result of the ballot for election to Council, however, may be recorded. The following were elected—T. Fletcher Robinson (Manchester), Henry Binns (Bradford), Frank Wright (Bolton), E. B. Fry (London), W. E. Baker (Manchester), H. Richardson (Bradford), A. Pollitt (Manchester), E. E. Cockcroft (Luddendenfoot), C. S. Ickringill (Bradford), and W. W. L. Lishman (Todmorden).

Appointment to Chair of Textile Technology—Manchester College of Technology

Mr. W. E. Morton, who has been appointed to the University Chair in Textile Technology in the College of Technology in succession to the late Professor W. Myers, was educated at St. Bees School and at the Manchester College of Technology. He graduated B.Sc.Tech. with First Class Honours, and in the next year obtained the degree of M.Sc.Tech. by a research on Fabric Structure. Since then he has been on the staff of the Cotton Industry Research Association at the Shirley Institute, Didsbury, Manchester, where he has been particularly concerned with the technical side of the problems which it is the object of that Institute to solve. Much of his time has thus been spent in numerous mills investigating the practical side of problems which the Shirley Institute has then to deal with on their scientific sides. Not less important has been his work of interpreting the scientific results of the Institute to the cotton industry, and of maintaining a close liaison between science and industry. The experience thus gained should be valuable in his new appointment, where he will be responsible for the training of many of the young men to whom the industry will look for future development. Mr. Morton has himself contributed to the new knowledge of raw cotton and yarns, which the Shirley Institute is acquiring for the benefit of the cotton industry; he has first-hand knowledge of Continental methods, and he represents the Cotton Research Association on the Government Committee on Aircraft Fabrics. Mr. Morton is a member of the Textile Institute, and was an early and successful candidate for its Associateship.

REVIEWS

Dyeing with Coal-tar Dyestuffs. By C. M. Whittaker, Bailliere, Tindall & Cox, London. Second edition 1926 (x. +248 pp., with Index, 2 plates. 10s. 6d. net).

It was at once evident when the first edition was published about eight years ago that this book would fill a definite gap in the literature available to practical dyers, and the appearance of this second edition shows that its value is appreciated. The author has succeeded in bringing his book up-to-date, and the recent developments in azoic and vat dyestuffs have received attention. However, so few changes in methods of dyeing have taken place recently that the new volume is largely a reprint of the earlier one. The application of basic, acid, mordant, direct, azoic, sulphur, vat and oxidation dyestuffs to all classes of textile materials including union fabrics, jute, straw and fur, is described in a thorough and practical manner. In view of Mr. Whittaker's experience in the dyeing of artificial, particularly viscose, silks, it is important to note that the new edition contains a well written and comprehensive account of this new branch of dyeing. Practical dyers of artificial silks will find this portion of the book particularly valuable, although the space devoted to cellulose acetate silks is somewhat brief.

A few features of the book invite comment. In view of the practical character of this work one would expect dyeing faults to receive greater attention. It is true that methods by which faulty dyeing may be avoided are described, but a dyer confronted with spoilt goods is very thankful to anyone who can assist him to trace the faults and indicate how they may be corrected. It is surely a mistake to suggest (page 70) that cotton piece goods are usually crabbed before dyeing, and it is doubtful (page 116) whether white worsted border fabrics are nearly always mercerised, especially before dyeing with sulphur black. Although the author disclaims any special knowledge of Turkey red dyeing, it is scarcely fair to omit the summary of methods contained in the first edition and then refer readers to out-of-date manuals. In connection with colloid theories of dyeing (page 63), attention might well have been directed to the interesting researches of R. Auerbach and R. Barlunek.

It should be made a punishable offence for modern technical authors to make quotations without giving the corresponding references; this applies to the American census mentioned on page 121, and it should furthermore be noted that figures relating to the British production of dyestuffs for 1924 have been available for several months. The reviewer does not agree that the difficulties of dyeing cotton-cellulose acetate silk union fabrics in two colours to desired shades requires the adoption of a two-bath process, with its accompanying extra cost. In view of the statement (page 181) that cotton material being dyed Aniline Black by the copper process is dark green after ageing, it must be a slip on page 182 which leads the author to state that fabrics dyed by the prussiate process are less fully developed after steaming; steaming carries the formation of Aniline Black to a very advanced stage. The tests described on page 241 for distinguishing between sulphur, direct, logwood, and Aniline Blacks should now include Azoic Blacks, and many readers would welcome more information than is given relating to methods for dyeing furs. The book is thoroughly recommended to all interested in dyes and dyeing. A. J. H.

The Wool Year Book 1926. Marsden & Co. Ltd., Manchester (pp. 583, price 7s. 6d.).

The compiling of an industrial Year Book is no mean task; the constant modernising of such a publication must entail an enormous amount of work. The energy expended in the production of the Wool Year Book has been amply justified; it maintains its usual high standard and well merits its position as a work of reference. An interesting annual review of the worsted and woollen industries is provided, and the various sections of the book dealing with raw materials and their conversion into yarns, fabrics, and knitted goods are extremely well written. The chapters on bleaching, dyeing, printing, and finishing contain the right amount of information to enable spinners and manufacturers to understand the nature and functions of the various after-processes through which their goods pass. The general "get-up" of the 1926 edition is, as usual, beyond reproach. Diagrams are well reproduced. A useful amount of statistical

information is given, and the clear exposition of trade customs and usages will be of value to those engaged in the allied textile industries. In the sections dealing with textile calculations, every effort has been made to render the various processes readily understandable. When one compares the somewhat crude mathematical efforts of the textile technologist with the more highly polished and efficient methods of the physicist and engineer, however, one feels the need for the inflexible inclusion of a course of higher mathematics in the training of the former. F. L. B.

Some Parasites of British Sheep. By W. C. Miller. Robert Young & Co. Ltd., Glasgow (price 2s. 6d.)

This small book makes available the essentials from one branch of zoology that bears on the textile industry. It deals with the British insect and arachnid parasites of sheep, as well as certain other afflictions of those animals, especially those which can be treated by dipping. The writer is a lecturer in the Royal (Dick) Veterinary College and in the Edinburgh and East of Scotland College of Agriculture. The book is brought out by a well-known firm of manufacturers of sheep and cattle dips. It is estimated that the loss accruing annually to the British sheep farmer—loss of condition in the sheep themselves, damage to hides and wool, or actual deaths—is not less than £2,500,000, although this loss is spread over a sheep population of some twenty millions. There is thus a short limit to the money that can profitably be spent in control measures, but in some cases, and these are emphasised by the writer, greater use ought to be made of proved methods. A knowledge of the life history of a parasite is fundamental to methods of eradication or control. Several of the parasites discussed in this book afford examples of the application of such knowledge. One stage in the life history may be much less vulnerable than the others. The eggs of the sheep scab mite are unharmed by dips fatal to the mite itself. The eggs hatch in from three to seven days after deposition. Dipping a second time after seven to fourteen days allows time for the hatching of the eggs present at the time of the first dipping, but the young mites are not then old enough to lay eggs themselves. The female sheep ked deposits larvæ instead of eggs, and the larvæ pupate immediately. Inside its hard case the pupa is not destroyed by dipping. The pupal period lasts from 19 to 24 days, and the young female deposits her first larva 12 or more days after emergence, so that again the appropriate time for the second dipping is determined in the light of the life history.

The writer allows it to be apparent that one aspect of human nature has proved something of a trial to him. Economic entomology, though very fascinating, is a tantalising sphere of activity. Often enough one is unable to prescribe really practicable or effective control measures, but where advice can be given, which, if followed, would be priceless, one encounters problems in psychology. Sheep scab is a case in point. In Great Britain, says Miller, the disease is difficult to eradicate because in some parts the geographical features of the country are of such a nature that it is extremely difficult to collect all the sheep from them for the periodic dippings which are necessary to effect eradication. Sheep scab having been eradicated in Australia and New Zealand by stringent legislative measures, it is felt to be rather a reflection upon British sheep owners and those responsible for the framing and execution of live stock regulations, that sheep scab is still a serious menace in Great Britain. Miller has no doubt that scab could be absolutely eradicated if every sheep in the country could be dipped three times in three weeks, and if regulations to prevent its reintroduction from other countries were rigidly enforced. Foot-rot is another disease that is allowed to do a lot of avoidable damage. The writer points out that by a periodic run through a foot-bath of, for example, copper sulphate solution, sheep on farms notorious for the prevalence of foot-rot can be kept free from this disease to a very large extent. But too few flockmasters take advantage of this simple method. The result, in addition to loss of condition, is a great waste of the shepherd's time in catching and treating lame sheep.

Other pests that take a large toll on the shepherd's time are sheep maggot flies. In summer the time spent merely in watching a flock for indications of the irritation caused by maggots is in the aggregate considerable. These flies, which belong to three species, breed normally in the flesh of an animal that has died out in the open, but not infrequently make use of living sheep, for the

most part animals with dirty hindquarters. The various methods employed against maggot flies, as well as those directed against ticks, are not of a very radical kind. Perhaps the idea of completely avoiding attack by bluebottle and greenbottle flies is chimerical, though one is tempted to hope that knowledge of their reactions to odours or other stimuli might lead to some neat method of defence. The remarkable fact is dwelt upon by Miller that if dead or decomposing fleshy material be left lying in the open almost any time between May and early September, anywhere whatever, in town or country, it is almost certain to be used as a maggot nursery within 36 hours. A problem like this is a challenge to the wits of the entomologist.

The author has done good service in bringing together the information about sheep parasites which is made available in so convenient a form in his book. It is very useful, on the one hand, to have defined the directions in which propaganda is required, and, on the other, to have the problems indicated which call for research. Not all of these problems have been touched upon in the present review. To tackle maggot flies will be difficult, though intriguing. Treated as they have to be by flockmasters with universal respect, it would seem of pressing importance to learn everything possible about them and their ways. F. W. D.

GENERAL ITEMS AND REPORTS

Linen Industry Research Association

The sixth annual general meeting of the Linen Industry Research Association was held at Belfast on Tuesday, 23rd March, under the chairmanship of Mr. J. G. Crawford.

The report of the Council and statement of accounts were adopted on the motion of Mr. M. B. Lamb, seconded by Mr. W. H. Webb.

The retiring members of Council were re-elected on the motion of Mr. A. Scott, seconded by Mr. J. Grey.

Dr. J. Vargas Eyre, the Director, addressed the meeting, and his utterance was of a valedictory character. He was, he regretted, speaking for the last time in his official capacity as director, having accepted another engagement in Ireland. He emphasised the importance of greater knowledge of flax, the linen industry's raw material. Much had been done during the past six years in laying the foundations, evolving better methods, and in gaining experience in tackling special problems. It was now known which of the chief characteristics of the flax plants were predominantly inherited and which were mainly influenced by environment, so that future work in that connection would be conducted with greater certainty and speed. He looked optimistically forward to the future of the industry's research efforts, and unless their staple industries could be placed on a more scientific basis they would not be likely to retain supremacy. If he had been able to contribute in any way towards that condition, thanks were due largely to the members of the Association for their patience and confidence and to the staff for the soundness of their work and their studied efforts to make their institution a success.

The annual luncheon followed in the Carlton Hall, when Mr. James G. Crawford again presided over a large and influential company, the guest of honour being the Prime Minister, Sir James Craig.

The Chairman expressed gratification on account of the attendance of the Prime Minister, whose presence indicated his esteem for the Research Association. He (Mr. Crawford) proceeded to speak as to the position and progress of the work in connection with J. W. S. pedigree seed. Uniformity was one of the most outstanding characteristics of pedigree flax, and this quality would greatly minimise faults in spinning, weaving, and bleaching, and in saving waste and thereby cheapening the product. The linen industry had often been described as unprogressive, but he believed that if the institute at Lambeg was adequately supported, it was capable of furnishing the information required by the industry to place it on sound and progressive lines. Some day, he hoped, the renaissance of the linen industry would be said to date from 1919, when the Research Association was founded.

In conclusion, Mr. Crawford referred to the impending departure of Dr. Eyre, and said their only consolation was in the thought that it was the success of

Dr. Eyre's labours for the Association that marked him out for his new appointment.

Mr. H. L. M'Cready also spoke, and thanked the Imperial Government and the Northern Government for their assistance for the Association. He also joined in the expression of regret on account of the resignation of Dr. Eyre.

The Chairman, in calling upon the Prime Minister, spoke appreciatively of the assistance from the Government of Northern Ireland. The last mark of interest in and approval of the efforts to provide pedigree seed for Northern Ireland was their sanction of the purchase of de-seeding machines, which, on the basis of experiments conducted in 1925, bid fair to go a long way towards solving the question of seed saving in Ireland. He did not believe that would close the benefits derivable from the Northern Government. Finally, he pleaded for whole-hearted co-operation on the part of the Department of Agriculture and the Research Association.

Sir James Craig, Prime Minister, addressed the gathering, and said it gave him the greatest possible pleasure to meet again those who had been helping during recent trying years the industry on which he might almost say Ulster was founded. He wished Dr. Eyre every success in his new sphere of action, and also congratulated their Chairman (Mr. Crawford) upon his new honour in being appointed Consul for France. He had no doubt that the Research Association must prove of invaluable assistance to the industry by way of research in the right direction. He was convinced that, if they carried on as they had done in the past, the scientific investigation engaged in would be of enormous assistance to the industry. If there was the slightest difficulty in giving them all the financial assistance they required, it would not be owing to lack of sympathy on the part of the Government, but simply owing to safe procedure in finance and avoidance of anything that might hamper Ulster's trade in the future.

Mr. W. H. Webb proposed a vote of thanks to the Chairman and to Sir James Craig, and appealed for more widespread support for the Association.

The report of the Council falls naturally into two parts, viz., that dealing with the organisation, administration and finance of the Association, and that dealing with the research work accomplished, in hand, and in contemplation. It states that during the greater part of the financial year 1924-25, which period the report covers, the gravest anxiety was felt as to the financial position on account of the continued trade depression. To add to the anxiety the recasting of the Association's finance had to be undertaken as the end of the first quinquennial period during which a fixed arrangement with the Department of Scientific and Industrial Research had been in operation, was concluded. Protracted negotiations with the Department proved necessary before arrangements upon which the second five-year period could be commenced were made. The Council are now able to announce that satisfactory arrangements have been made which can be prosecuted successfully only if adequate co-operation and support be forthcoming from the trade. The practical issue desired is an increased membership. Of no little interest are the details given of means adopted to broaden the interest in the work of the Association, and perhaps the most valuable of these is the policy of having "open days" upon which representatives of the trade visit Lambeg and take part with increasing frequency in discussions on such topics as the production of fibre and of seed by the flax plant; further bleaching experiments; and tests for acids, chlorine, &c., in linen goods. The work of the Seed Bulking Committee is referred to, as is also the establishment of the Flax Industry Development Society, Ltd. This scheme is rightly described as "a highly important step towards securing more remunerative crops of flax both at home and in other parts of the Empire." The report then proceeds to deal with research work, and experiment work on the growth of flax is first referred to. The effect of varying the sowing conditions, of different widths between the drills, of different rates of sowing, and of using samples of seed of different germination capacities has been studied, and it is believed will prove of great value in flax cultivation generally. A seed separating machine made by Messrs. P. K. Arm, of Belfast, for the Association, has been very successful in its tests, and a large scale trial is to be given to the machine under the auspices of the Ministry of Agriculture of Northern Ireland. During the past year a sorting machine has been brought to a stage where exhaustive tests can be carried

out upon the machine, and the results have proved satisfactory. It is now being employed in a comprehensive study of the degree and character of the breakdown of flax fibre strands during preparing. Comparative records have been secured of the behaviour of yarns under a load applied and removed slowly and under the comparatively quick application and removal of loads in the loom, and so far the records show that the relative properties of the yarns determined in these two ways vary in a parallel manner. Progress has been made in the experimental investigation of a number of bleaching problems, and some of the results arrived at will shortly be published. Additional work upon sizing and finishing problems has been done, using the testing machines developed at the Institute. Altogether the report justifies the statement that the position occupied by the Association's Institute among other industrial research organisations is a high one.

Heredity in the Mule*

"I have no faith in anything short of actual measurement and the rule of three." These words of Darwin might have been taken by Porcherel as his text in attacking the problem, "How should the hereditary characters of the mule be interpreted ?" He has been concerned especially with two types of mules, those of Poitou and those of the Setif region of Algeria. He has made a very carefully planned series of measurements of mules of the different groups and of the asses and mares of the breeds used to produce them, in some cases being able to examine parents and offspring. It may be said at once that Porcherel's methods are more important than his results. Fundamental problems assuredly are involved, but the material is not favourable for their solution. One recalls how Nathusius, who made admirable studies of the coats of sheep and other mammals, examined the hairs of mules and their parents. He found that fibre structure was sometimes intermediate, but sometimes more resembled that of one parent than the other. That was before the close of the last century, while Mendel's work was still undiscovered. Nathusius thought that possibly that method might serve to bring to light principles of heredity, though he did not regard his own results as carrying him very far. Precisely because the cross is so wide one may hardly hope for convincing results in Porcherel's work. His general conclusions may be briefly quoted. It makes a great difference what breeds of asses and mares are brought together. The distribution of paternal and maternal characters in the hybrids shows very great variability. Characters intermediate between those of the two parents are always more in evidence than those received from the ass. In the Poitou mules the characters received from the mares predominate, sometimes in a very evident manner; the same is true in some cases with Algerian mules. It is emphasised that the greatest care should be taken in choosing the mare for mule production. Porcherel is under the disadvantage of having to deal with a cross between species, while within each breed of horse or ass he found a large amount of variation. Furthermore, he is concerned with characters of a kind the inheritance of which is very difficult to interpret, even when the geneticist is able to choose the most convenient material. Thus, in the rabbit, Castle has obtained data by crossing large and small breeds, which he would explain by postulating as many as ten Mendelian factors. Whether the size of a particular part of a rabbit is determined chiefly by factors affecting the general size of the body, or mainly by factors that produce their effect upon that special part, is a subject upon which there is disagreement. In deermice, after prolonged studies of the genetics of the size of parts of the body, Sumner even doubts whether his results are to be explained purely on Mendelian lines. With the mule there is yet another complication. In plants wide crosses often produce remarkably vigorous offspring. Opinions differ about the significance of this, but the fact itself is well known. The mule is the stock example of the same thing in animals. Although sterile, it is hardier than the horse and does more work on less food. Incidentally it may be mentioned that a similar effect may be one of the advantages of crossing certain breeds of sheep. The facts which have just been touched upon cause a student of heredity, even though desirous of producing results in the workaday

* Porcherel, E.—*International Review of the Science and Practice of Agriculture*, New Series, 1925, **3**, No. 4, pp. 982-1002.

world, to wonder how he can most usefully spend his time. At the present stage of our knowledge of heredity, if economic work be undertaken, less complicated problems than that tackled by Porcherel should be selected. It would appear from Porcherel's paper that he is not very conversant with modern work in genetics, but it is clear that he has an eye for the form of an equine which commands the respect of one mainly concerned with microscopic characters in small animals. He is Director of Zootechnical Research in the National Veterinary School at Lyons. He has worked out a very thorough scheme of measurements of parts, and of indices to show the comparative size of parts. For example, the thoracic index is expressed by the relation between the greatest width of this region and the height; the dactylo-thoracic index is the relation between the perimeter of the skin and that of the thorax. Similar methods might well be employed in the study of problems of inheritance in sheep or other domestic animals. In work on crosses between breeds, or on the inheritance of structural characters within a breed, he might hope for more definite results. A worker in pure genetics is not likely to have Porcherel's intimate knowledge, combined with appreciation of form, of such an animal as the horse, nor is it probable that a practical breeder, equally qualified in those respects, would be capable of expressing the characteristics of different animals in terms of series of comparable measurements and ratios —F. W. D.

Dyestuffs (Import Regulation) Act 1920—Application for Licenses

The following statement relating to applications for licenses under the Dyestuffs (Import Regulation) Act 1920, made during the first three months of this year, has been furnished to the Board of Trade by the Dyestuffs Advisory Licensing Committee. The total number of applications received during January was 581, of which 509 were from merchants or importers. To these should be added 24 cases outstanding on the 31st December, making a total for the month of 605. These were dealt with as follows—

Granted, 475; referred to British makers of similar products, 96; referred to reparation supplies available, 16 ; outstanding on 30th January 1926, 18.

The total number of applications received during February was 549, of which 476 were from merchants or importers. To these should be added 18 cases outstanding on the 30th January, making a total for the month of 567. These were dealt with as follows—

Granted, 475; referred to British makers of similar products, 65; referred to reparation supplies available, 7; outstanding on 27th February 1926, 20.

The total number of applications received during March was 592, of which 515 were from merchants or importers. To these should be added 20 cases outstanding on the 27th February, making a total for the month of 612. These were dealt with as follows—

Granted, 516; referred to British makers of similar products, 60; referred to reparation supplies available, 11; outstanding on 31st March 1926, 25.

Of the total of 1,794 applications received, 1,589, or 88 per cent., were dealt with within seven days of receipt.

THE JOURNAL OF THE TEXTILE INSTITUTE

Vol. XVII MAY 1926 No. 5

PROCEEDINGS

SIXTEENTH ANNUAL GENERAL MEETING, AT MANCHESTER, 21st APRIL 1926

This meeting took place as stated at the Institute premises, Manchester. At the outset the chair was occupied by the retiring President, Mr. John Emsley, J.P., who was supported by the President-elect (Mr. Wm. Howarth, J.P.), Col. F. R. McConnel, W. Frost, T. Fletcher Robinson and others, there being an attendance of over thirty members.

It was unanimously agreed that minutes of previous annual meeting, as circulated at the meeting, be taken as read and approved.

THE ANNUAL REPORT OF THE COUNCIL

Mr. S. B. Hollings (Bradford) moved, and Mr. W. Heaps (Bolton) seconded, that this report, as circulated, be adopted, and the motion was carried unanimously.

The report, together with balance sheet and accounts (1925), was as follows—

Although the progress of the movement represented by the Textile Institute has not been rapid, yet a steady rate of advancement, since its formation in 1910, has been maintained. The past year provided an unprecedented record of attainment in several directions. Of paramount importance is the reconstruction of the organisation under the terms and provisions of a Royal Charter of Incorporation, granted by His Majesty's Privy Council in March 1925. The decision to embark upon an effort in this direction was not arrived at without prolonged and anxious consideration, and the fact was not overlooked that the advantages to accrue therefrom must be associated with greatly increased responsibilities. It was always contemplated by the promoters, and the early supporters, of the Institute movement, that in addition to the provision of a definite platform for the consideration of scientific and technical problems, together with publication facilities, some form of certification of qualification should be available in connection with membership. Not until 1922, after the election of Mr. John Emsley, J.P., of Bradford, to the position of President, was any practical step taken in the matter. Mr. Emsley early sought means to contribute something of lasting benefit, and, having once decided in favour of supporting an endeavour to secure a Royal Charter empowering the Institute to grant diplomas in reference to "the practice, teaching, or profession of textile technology," spared neither time nor generosity in seeing the project carried through, kindly accepting office for four consecutive years for this purpose. Recognition has been already extended to the President in respect of his services and generous action in meeting the entire cost of the application for the Institute's Charter, as well as other incidental expenses, but the Council cannot permit the issue of this record without expressing warmest appreciation of the President's successful endeavour.

INSTITUTE DIPLOMAS—The Institute is now constituted an examining body concerned with certification of post-graduate qualifications for members by the issue of Diplomas of Associateship and Fellowship. Applications have come forward in considerable number, and the first awards will be announced at the Annual General Meeting. The Selection (Diplomas) Committee has a task which is by far the most exacting yet imposed on any Institute Committee.

Whilst certain more or less definite decisions as to procedure have been reached, yet the Committee is proceeding cautiously in the matter of precise regulations, preferring to rely upon the actual terms of the Bye-laws and to build up subsidiary regulations as experience in dealing with early applications may dictate. For the present, at any rate, all possible consideration is being given to possession by applicants of qualifications by well-established examining authorities, always provided that the claims of applicants in respect to engagement subsequent to training or graduation can be regarded as satisfactory. Already, special examination in general knowledge as to textile technology has been imposed in reference to a number of applications. The Committee is encouraged by the fact that this condition has been readily accepted by the majority of applicants affected.

ANNUAL CONFERENCES—Two general conferences were held in the past year—the one in connection with the Annual General Meeting at Manchester, in April, and the other at Edinburgh. This was the second time at which the annual movable conference has taken place in Scotland, and although the attendance was not quite up to the average, yet it was satisfactory and the event was highly successful. The Lord Provost of Edinburgh gave a reception to the members and visitors at the outset of the proceedings, whilst the concluding item of the visit took the form of excursions to Galashiels and Dunfermline respectively. Excellent arrangements were made at each place and various works were inspected. Those concerned with the arrangements and with the hospitality provided have already been warmly thanked for their generous co-operation. The conference at Edinburgh was held during Whit-week, and in view of the experience that this is a highly favourable time of year for the holding of such an event, the 1926 conference was to have taken place during Whit-week at Buxton, but in view of the industrial situation was cancelled.

JOURNAL OF THE INSTITUTE—It was pointed out in the Council Report of 1924 that to maintain the magnitude of the *Journal* during 1925 at the point reached the year before would present a serious financial problem. To aid in achieving, as far as possible, this desired result, it was decided to prepare, firstly, an estimate of expenditure and income, and, secondly, a quarterly statement of actual income and expenditure, so that progress could be controlled. The Council had asked that a sum £350 less than the expenditure for 1924 should be regarded as a maximum expenditure for 1925, and the estimate referred to above was based upon this request. While the Proceedings and Transactions Sections of the *Journal* were both less than the same Sections in 1924, the Abstracts Section, which provides a service of increasing value, exceeded any previous year. At the same time, by attention to every aspect of expenditure, and by a very welcome addition to the income of £100 from the Linen Industry Research Association, which made no grant in the previous year, it was ultimately found possible to produce the *Journal* during 1925 for an expenditure of £556 less than for 1924. The Research Associations have given continued support not only by financial assistance, but by valuable services on the Publications Committee—without this aid the work would suffer appreciably.

INSTITUTE HEADQUARTERS AND OTHER OFFICES—The headquarters premises of the Institute at Manchester are becoming a centre of growing activity and the Council continues to extend facilities for meetings to various organisations concerned directly or indirectly with the textile industry. The Members' Room at the Institute is visited by members with increasing frequency and facilities for refreshments are now fairly well established. In connection with the London offices and rooms, at 38 Bloomsbury Square, W.C.1, the suggestion which has frequently arisen in favour of some scheme of joint accommodation has taken definite shape during the past year. In addition to the Institute, with its particular accommodation for the London Section, the premises are utilised, under joint arrangement, by the Association of Special Libraries and Information Bureaux. For 1926, also, some accommodation is also provided for the British Institute of Industrial Art. The full effect of these arrangements will be better known by the end of 1926, but it is now certain that advantages will arise and the expenditure of the London offices and rooms will be considerably reduced, so far as the Institute is concerned. The Council desires to record its great appreciation of the earnest endeavours of the London Section Committee in the direction of the ultimate attainment of self-supporting conditions in regard to purely Section affairs. In connection with the Yorkshire Section of the Institute,

too, an arrangement has been made whereby the services of an Assistant Secretary, with his own office address (Mr. F. R. Thurlow, Sykes' Chambers, 37a Ivegate, Bradford), have been secured.

DESIGN AND STRUCTURE OF FABRICS—The Annual Competitions for advanced textile students at technical colleges, schools, &c., under the Institute's Crompton Scheme, has proceeded satisfactorily, and the work presented by the 1925 competitors was regarded as distinctly progressive. A total sum of £110 was distributed in prizes, and for the first time a special award of £10 was made in respect of the production of a single specimen of cloth of original and novel texture. It is interesting to note that the first prize (£35) in the general competition was awarded to a student-competitor from the Bradford Technical College. For 1926, the Institute range of prizes is extended by the addition of special competitions for yarns. Messrs. R. Greg & Co. Ltd. (South Reddish, Stockport), have generously agreed to contribute £25 per annum for three years in order that prizes may be offered for competition in yarns, the object being to encourage students in the spinning departments of technical colleges and schools. The scheme is experimental and the results will be watched with interest.

TEXTILE SOCIETIES AND KINDRED ORGANISATIONS—The Institute continues to provide facilities and secretarial services for occasional conferences of representatives of Textile Societies and Kindred Organisations in the various textile areas. Two conferences of delegates were held during the year—in February and October—and it is felt that a good deal of useful service is performed in this connection. The meetings have been proved of considerable benefit to all concerned, and it is believed that there is a distinct field for mutual co-operation on various matters.

FOUNDATION FUND—This fund continues to expand even though the rate of progress of building up a fund of the strength originally aimed at is somewhat slow. The total amount to the credit of the fund, as shown in the balance sheet, is £9,853 7s. invested in War Stocks, whilst £25 in cash remained at the bank. In addition to these amounts, there is £1,000 of War Stock and £1,500 of 4% L.M. & S. Railway Preference Stock, which refer to the Crompton Prize Fund Scheme. Taking the Crompton contribution at the nominal figure of £2,000, the total of the Foundation Fund at the end of the year reached £11,878 7s. The actual new contributions during 1925 were—£500 from Messrs. Courtaulds, Ltd., and a contribution of £25 from Mr. E. A. Swift, of Bradford. A further donation has been received, in 1926, of £83 4s. 7d. from the Cotton Textile Industry Committee (Wembley Exhibition).

COUNCIL AND COMMITTEE MEETINGS—The following is the record of meetings held during the year (1st January to 31st December 1925)—Council, 12; Selection (Diplomas), 13; Publications Committee, 11; Propaganda, 9; Finance, 6; Yorkshire Section, 8; London Section, 11; Lancashire Section, 1; Crompton Prize Fund, 4; Total, 76; as against 48 in the previous year. In addition to the foregoing, two Sub-Committees met for the consideration of special matters.

SECTION MEETINGS AND LECTURES—Seven meetings of the Lancashire Section and one joint meeting, two of the Yorkshire Section and one joint meeting, and 10 of the London Section were held during 1925, at which papers were read and discussed.

MEMBERSHIP—The membership list at the end of 1925—to be carried forward to 1926—was made up as follows—Honorary Members, 9; Life Members, 21; Members, 1,179; Junior Members, 64; Non-subscribing Members, 2; Total, 1,275.

The totals for the foundation year (1910) and the years 1918 to 1925 were—1910, 233; 1918, 612; 1919, 724; 1920, 856; 1921, 904; 1922, 994; 1923, 1,039; 1924, 1,083.

The Council lament the loss by death during the past year of Thomas Smith (Accrington); William Myers (Manchester); William Greenwood (Oldham); Robert M'Keown (Belfast); Peter Scott (Hawick); C. Greenwood (Huddersfield); George E. Mallott (Preston); E. H. Gates (Bradford); J. L. Lumsden (Freuchie, Fife); J. L. Smith (Huddersfield); James Marsden (Bolton); J. Pogson (Lytham).

AUDITORS' REPORT TO MEMBERS

We report to the members that we have examined the above Balance Sheet together with the books and vouchers of the Institute and that we have obtained all the information and explanations we have required.

We further report that in our opinion the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the Institute's affairs according to the best of our information and the explanations given to us, and as shown by the books of the Institute.

56 Mosley St., Manchester. *Incorporated Accountants, Auditors.*

THE HON. TREASURER'S ANNUAL REPORT

The Hon. Treasurer (Mr. T. Fletcher Robinson) presented his annual report as follows—

In presenting my twelfth annual report, I have continued comparison of items as in previous years in order that members may easily make examination of the accounts.

FOUNDATION FUND—There has been an increase of £501 1s. during the year, £500 of which represents a generous donation from Messrs. Courtaulds, Limited, the total of the fund being £9,853 7s. on 31st December 1925. There has been received since, £25 from Mr. E. A. Swift, of Bradford, and £83 4s. 7d. from the Cotton Textile Industry Committee (Wembley). For all these donations the thanks of the Council have been tendered.

JOURNAL ACCOUNT—The expenditure is £3,816 4s., being £213 11s. 8d. less than 1924, the income being £3,102 3s. 11d., leaving a deficit on working account of £714 0s. 1d., which is £554 19s. 8d. less than 1924. Twenty-five per cent. of the total members' subscriptions, £590 16s. 8d., and a transfer from the Foundation Fund interest of £123 3s. 5d., balances the Journal account.

Grants were received from Research Associations—Cotton, £300; Wool, £150; Linen, £100; total £550.

The receipts from advertisements and subscribers were £1,434 17s. 1d., being £333 10s. 5d. more than 1924. There was an increase under this head in 1924 of £265 3s. 8d., making an increase in the last two years of £598 14s. 1d.

The cost of printing the *Journal*, and postage and reprints, was £2,147 1s. 10d., being £375 11s. 10d. less than 1924. An increase of £50 in the Editor's salary makes the cost under this head, with secretarial contributions debited as £60, into £510, as against £460. Wages (clerical and advertising) are £6 11s. more, and there has been an additional cost for stationery of £19 3s. 1d.

The cost of purchase of *Journals* and general expenses is £17 16s. 1d. less, whilst travelling expenses are £19 5s. more.

Literary contributions and abstracts, together, have cost £87 19s. 8d. less.

This year the sum of £26 13s. 1d. has been debited to *Journal* Account as a proportion for heating, lighting, and cleaning. Advertisement canvassing commission has cost £51 3s. 3d., being £8 2s. more.

There is no prospect that the expenditure on the *Journal* will be any less in 1926; on the contrary, there will be considerably more expense, because there will be many more papers to be published consequent upon the contributions from applicants for Institute Diplomas, besides anticipated increase of original matter from Research Associations.

REVENUE ACCOUNT—The cost of obtaining the Royal Charter was £650, which amount has been paid by our President, Mr. Emsley, to whom the Council has expressed special appreciation. The income from members' subscriptions is £2,384 6s. 2d., from 1,105 members, being £118 7s. 10d. more than in 1924 from 960 members. Salaries and wages on revenue account are £725, being £33 15s. more than in 1924. Travelling and meetings cost £70 6s. 11d., an increase of £21 12s. 8d. on 1924. Printing, stationery, postages, and telegrams cost £251 13s. 6d., being £101 3s. 4d. more than the previous year.

London Section expenses have been £497 16s. 4d., being £90 19s. 10d. less, the members in the London Section numbering 193, as against 142. The contribution from the Special Libraries Bureaux for joint use of the rooms for seven months has reduced the expense by £77 7s. 10d. For 1926 an arrangement has been made with the Institute of Industrial Art, from whom there will be a further income. For the full year 1926, from these two organisations, we expect to receive about £175.

The interest from the Foundation Fund, £487 16s. 8d., has been transferred as follows—to Revenue A/c £339 13s. 3d.; Journal A/c £123 3s. 5d.; and for the Mather Lecture £25.

The definite income for 1925 is £2,384 6s. 2d., and interest from Foundation Fund £487 16s. 8d., making a total of £2,872 2s. 10d., being £126 15s. 10d. more than 1924.

Receipts from members' subscriptions have been—1917, £851 2s. 6d.; 1919, £1,394 5s. 5d.; 1922, £1,694 14s.; 1923, £2,136 13s. 6d.; 1924, £2,265 18s. 4d.; 1925, £2,384 6s. 2d.

Membership at 31st December 1925, was 1,275, being an increase of 192 members on the year. The expenditure for rent, rates, heating, lighting, and cleaning compares as follows—1918, £219 3s. 11d.; 1920, £221 9s. 5d.; 1922, £300 19s. 5d.; 1923, £271 7s. 9d.; 1924, £298 7s. 2d.; 1925, £293 8s. 8d. The cost of salaries and wages of staff (including *Journal*) has been—1918, £453 12s. 6d.; 1920, £1,144; 1922, £1,465 5s.; 1924, £1,248; 1925, £1,363 5s.

SUMMARY—After meeting from the Foundation Fund interest the deficit on the *Journal* of £123 3s. 5d., and the deficit on Revenue A/c of £339 13s. 3d. there remains a balance to credit of Revenue A/c of £132 19s. 11d. to be carried forward to 1926.

CROMPTON MEMORIAL FUND—The income from invested funds has been £94, and from subscriptions from education authorities for Albums £130 13s., this latter being £35 10s. less than for the previous year. The balance in hand on 31st December last is £146 16s. 10d.

DIPLOMAS—There have been already 123 applicants for Fellowships and 183 for Associateships, and £600 for fees has been received up to date. The problem of how the money from Fellowship fees should be allocated is receiving the serious attention of the Council.

The financial situation at the end of 1925 is much better than at end 1924, and with careful management of the finances, and additional membership, due to increased interest as a result of the securing of the Royal Charter, the Institute should make a quick advance to greater usefulness and success.

The Hon. Treasurer also formally presented the balance sheet and accounts, as printed and certified by the Auditors, and moved that the Hon. Treasurer's report and the balance sheet and accounts be approved.

Mr. John Crompton seconded the motion, which was carried unanimously.

PRESENTATION OF DIPLOMA TO MR. J. H. LESTER

Mr. John Emsley, as the retiring President, stated that he had a very pleasant duty to perform before he relinquished office, namely, to present to Mr. J. H. Lester the Fellowship Diploma of the Institute. It was regrettable that illness prevented Mr. Lester from being present and receiving the Diploma personally. He was quite sure that all would agree with him in stating that Mr. Lester had rendered services to the Institute for which money would not have been adequate recompense. It was to be sincerely hoped that he would soon be restored to his normal state of good health and strength.

The Diploma, contained in a handsome leather wallet bearing a suitable inscription, was handed to the General Secretary (Mr. J. D. Athey) for transmission to Mr. Lester.

VOTE OF THANKS TO RETIRING PRESIDENT

Mr. John Crompton (Chairman of Council) proposed that a very hearty vote of thanks be accorded the retiring President, Mr. John Emsley, for the valuable services he had rendered during his term of office. It had been quite an education to be associated with Mr. Emsley, and his colleagues fully appreciated the good spirit and thoroughness with which he had undertaken his duties. Mr. Emsley's years of office had been prolonged owing to the delay in obtaining the Charter, and, of course, he could not be possibly released from his responsibilities until it was secured. It was probable that future generations would best be able to realise the value of that Charter, which, doubtless, ought to have been obtained many years previously. It was certain that it would be a fruitful means of contributing to the welfare of the textile industry, and it was largely owing to the vision of Mr. Emsley and his persistence and generosity that the Institute could now confer its Diplomas upon those who were deemed worthy to receive them. Mr. Emsley was one of the leaders of the textile industry whom they delighted to honour, and it was most certainly a proud moment for him when, some months ago at Bradford, he was presented with the first Fellowship of the Institute in the interests of which he had laboured so long and so conscientiously.

Mr. W. Frost (Vice-President) seconded, and said that when Mr. Emsley first came to them they knew very little about him. All that was known was

that he was a Yorkshireman, with all that the name implied, and that he was going to do the very best he could for the welfare of the Institute. The two things which were most impressive in connection with the work he had done, and which demonstrated the possession of certain fine qualities of character, were his optimism and his pertinacity in carrying forward anything he undertook. He had left his mark upon the work of the Institute, and had made it possible for it to fill a much wider field of services in years to come.

The motion was carried by acclamation.

Mr. Emsley, responding, said—Mr. Crompton, Mr. Frost and gentlemen, I have listened with very mixed feelings to the remarks which have been made about myself. I think, and I have always said, that anybody who has been in a position to get anything out of an industry should not think that he is entitled to it all, but that he should give something back to the industry. The textile industry, next to agriculture, is the greatest industry in this country. It is the industry that finds the bulk of our food, as 44 per cent. of the total of the goods that are exported are textiles. That means that the textile industry must shoulder a great responsibility, and that it must not, and shall not so long as the Textile Institute remains, take second place to any other section of the community. I have been very much impressed during my years of office with the fact that we have no salvation for this country except through science. The days of machinery were very great in this country, but machinery has played its part. Machinery, in my opinion, now takes a secondary place, and science will take the first place in industry. You may think that the industry has not taken up research work in the way that perhaps originally was intended, but its various branches have been forced to undertake such work and are making good progress. The Textile Institute, as the head authority, is able to co-ordinate all the various branches of the industry, and by the aid of our Charter we have lifted our industry from the position of a trade to the status of a profession. I hope that the country will realise that there are opportunities in the industry for its cleverest men. It is no longer necessary for a man to go into law, divinity, or politics. He can come now into a professional trade, and can do quite as much good, or even more good, through trade, than in other directions. The textile industry is a very complicated one. We have to live by our exports. We cannot grow sufficient food in this country to keep us, and we have to pay for the food which we receive from foreign countries by our industry; otherwise, we cannot keep our population in a reasonable state of prosperity. I look forward to the time when it will be no longer hard work for people to earn their daily bread. I believe that science will help to make the machine subservient to the human element to such a degree that the physical body shall not have to exert itself as much as it has exerted itself hitherto. but that the brain will take a bigger part in the affairs of life than ever it has taken before. I have always thought I would like to see the person who has to do the manual labour have a reasonable amount of time for instruction, for recreation, and for leisure, and for all the things that make life worth living. But what is the use of having that extra time and those added amenities unless our bodies are physically able to stand the strain of our work and also of our recreation ? I want to cut out as much physical labour as I can from our daily task and make it a pleasure, and therefore make our recreation, after we have done our physical toil during the day, a pleasure also. I believe that science will make this a wonderful world to live in. There was one gentleman in England who made the remark that we want this country to be fit for heroes to live in. I want it the same. I believe there is not a man in this room who does not share that wish. But we are only on the fringe of such a possibility. We have to make a healthy country and a clean country first. There is no more beautiful country in the world than England, and yet we are polluting it with smoke every day of our lives. The coal question is at the root of all our trouble—not in regard to the miners' question—but in the way that we use the gift that God has given to this

country and which is going to make or mar it. Science must solve this coal problem. It does not matter if it costs 100 millions of money to do it, it will be cheap in the end. We have untold wealth at our very doors, and we are wasting it like profligates. Perhaps the hard times that we have been going through during the past three or four years will waken us up to the fact that we must make a fresh start and take a bigger view of things than we have done hitherto. If that is going to be the case, then the Institute will play a very important part. My term is now passing, and I have other interests. I shall always remember with pleasure my term of office, and I shall always feel that I have learned more than I have given, because I have been mixing with gentlemen of big minds and big views. It has been said many times that it is not the man who knows the most but the man who adapts what he gets hold of who makes the most progress. Knowledge must not be merely stored up in the mind; it must be applied to utilitarian purposes. It is in the hard school of life that one learns the most. I am looking forward to the time when those who do not wish to assume the responsibility of managing a big business, but who have ideas and are thinking and are studying day in and day out, may be relieved from the dread of impoverishment while they are working out their ideals for the prosperity of the industry. I wish to say, in conclusion, that the President who is going to follow me is a remarkable man; you have made a wise choice, and you will have no regrets. I thank you for the vote which you have accorded me. It has been a great pleasure to be associated with you, and I hope and trust that the gentlemen who follow me in this office, like those gentlemen who have preceded me, will maintain the high standard that we have endeavoured to keep up.

ELECTION OF PRESIDENT

Mr. Emsley.—It is now my pleasure to move that we appoint Mr. William Howarth, J.P., as President of the Institute for the coming year. Mr. Howarth is the managing director of the Fine Spinners' and Doublers' Association. He has had a remarkable career. He commenced, like I did, at the bottom. He was a "half-timer" in 1871, so that he has passed through that phase of the industry. He worked in the mule gate at Bolton for years, and he ultimately accepted an invitation to join the Fine Spinners' and Doublers' Association, and he has attained the position of managing director. He leads the Bolton Master Cotton Spinners' Association as its chairman, and is a prominent member of the Federation of Master Cotton Spinners' Associations. He is interested in Empire cotton growing, and is a member of the Executive Committee of the British Cotton Growing Association of which he was one of the founders. He is also a member of the Council of the Empire Cotton Growing Corporation, and a director of the Liverpool Cotton Association. In Bolton, Mr. Howarth takes an interest in local affairs. He is a magistrate, a member of the Council of the Bolton Chamber of Commerce, and is associated with other public bodies in the Bolton area. He is an authority on various aspects of trade, and at the World Cotton Conference in 1921 he read a paper entitled "The Characteristics of Cotton Required by Spinners and the Present Defects in Raw Material." Gentlemen, you are appointing to-day as your President someone who stands head and shoulders above his compeers in the cotton industry. I think you are making a wise choice. I think he will do something that is required, and that by his encouragement of scientific investigation we shall be enabled to evolve order out of the morass which at present prevails in regard to cotton. As you are all aware, there have been rapid changes and violent fluctuations in regard to both cotton and wool, and it is to such gentlemen as Mr. Howarth that we look for the solution of the problems which confront us. Times are changing, and the artificial silk industry is now coming to the forefront as a result of scientific effort. In regard to flax and hemp, we must again turn to science for assistance in order that our trade may maintain the supremacy it has held hitherto

in those commodities. Once more I have very great pleasure in proposing that Mr. Howarth, whose credentials I have been reading to you, should be appointed our President for the ensuing year, and expressing the hope and assurance that he will lead the Textile Institute to a higher place than it has occupied before.

Col. F. R. McConnel.—It is a very great pleasure to me to be able to second the proposal that my friend Mr. William Howarth should be the President of the Textile Institute. I was little more than a small boy when I was first put to work in a cotton mill which is now part of the Fine Spinners' Association, and I have a great personal pleasure in feeling that the managing director of that magnificent concern should now become the President of the Textile Institute. We have had a most distinguished President who was on the wool side. We are now going in for cotton, and I do hope and trust that the deliberations which will be presided over by Mr. Howarth, as President, will have a lasting effect upon the cotton trade. We all know what a serious position it is in, and how much we long for good guidance as to the proper way of transforming what is certainly not a paying industry at present into one that is. I remember the old days of the Fine Spinners. They had their troubles, but they surmounted them magnificently, very largely owing to the skill and organisation of a previous President, Mr. Nixon. I do hope that just as the Fine Spinners surmounted their difficulties, so the cotton trade will be able to overcome theirs, and that the Textile Institute will take its part in helping to mould the higher form of thought necessary in connection with making the cotton trade once more equal to its old standard of world triumph. I do not think I need say anything more. It will be far better for us to listen to the new President making his presidential remarks. I am sure that at the end of his term of office we will all feel that we have done very wisely in electing Mr. Howarth as our leader.

Mr. William Howarth, J.P., was then unanimously elected.

THE PRESIDENTIAL ADDRESS

The President, in reply, said—Mr. Emsley, Col. McConnel, and gentlemen, we have been advised, in the best Book in the world, that it is very unwise to boast of one's self when putting on our armour; we should rather wait until we are putting it off. Consequently I do not feel capable of saying quite as much to you as I might say were I relinquishing this office. But I have one duty that I must first perform, and that is to thank you for electing me to this distinguished position—a position which does provide, as our retiring President has said, opportunities for service which, if they are not frittered away, may be of great advantage to the community at large. In the comparatively short life of this Institute, the Presidents and the Council who have guided its direction have accomplished a wonderful work. To-day we stand with a Charter empowering us to grant Diplomas. That privilege has been given to us not as an end in itself, but as a means to an end, in order that the Institute can widen its circle of operations and give greater service to the community than it has ever done before. In his valedictory address, Mr. Emsley has measured, very accurately and with a great degree of force, the importance of industry to this country. Personally, I have never permitted myself to be deluded with regard to that matter. There are people who think that banking, insurance, and the carrying on of the various services which are adjuncts to commerce are the important things in the industrial life of this country. From my point of view, they are merely services. If at any time we lose our industries, we shall lose our carrying power, our banking, our insurance, and all the other subsidiary ingredients of commercial organisation. Industry is the basis upon which the prosperity of this country rests, and we who have charge of industry must never allow ourselves to be led away from the acknowledgment of that main factor. We have to justify our Charter, and we have to consider how that may be done. We can see the drift towards associated or communal effort which is a phase of world thought at the present time. I think, now that that drift has come, it will be

a continual force in the life of the world. We, as an Institute, are part of that drift. We must bring our brains together to try and think out the problems of industry, for the purpose of evolving industrial systems which are essential, so that the commercial status that our forefathers built up for us may be maintained. The systems which have raised the nation to present grandeur and to opulence may not necessarily suffice to preserve it in its splendour for the future. We are the heirs of our fathers, and they were great men. I know that there are certain sections of our community who imagine that it was by luck that those who built up our textile trades hit upon the correct methods of accomplishing their end. In parenthesis, may I say that, as President of this Institute, I do not wish to be regarded solely as a "cotton" man. The Institute deals with all classes of textiles—silk, wool, cotton, flax, jute, hemp, and the new synthetic fibres or threads. They should all take equal importance in the mind of a President of an Institute such as this, and so far as I am concerned I shall seek to regard them in that way. But I was trying to tell you that I did not think that the men who built up the industry were ignorant men. They were men who knew all the facts with regard to the forces of nature and of mechanism that were available in their day. By skill, hard work, clear thinking, and the co-operation of those with whom they worked, they built magnificent edifices which for one hundred years have placed this country at the head of the industrial forces of the world. It is important that we should try to maintain that position in the textile world. We need not hide our heads when comparing our profession, as Mr. Emsley has called it, with any other profession practised in this country. I think all of you who have read the history of mankind will agree that the second commodity that mankind found necessary was clothing. We will not go into the nature of the clothing at this particular moment; but from that time forward mankind and civilisation itself, has depended upon the progress which has been made in textiles, in decorative work, and in clothes. In many ways the civilisation of the world has been proportionate to the advances made in the manufacture of textiles. I know that some folks will argue that the art of war has been the main influence in the progress of the world. Well, let them argue. In the early, rude ages of the world it may have been the main stimulant, but after a few ages the factor of clothing must be regarded as the main indication of the progress of civilisation. If there are any who do not believe this, I will recommend them to read a book which used to be read very much in other days—Carlyle's "Sartor Resartus." But the main start in textile industrial progress was not brought about by accident, but by hard work. I want to pay tribute to those teachers who, 40 or 50 years ago, gave the best of their lives and their intelligence for the education of those who were to carry on the trade of this country. Those men had not the equipment or the scientific point of view that our present teachers possess, but they were earnest men with a constructive point of view and a high moral purpose. They endeavoured to instil into the minds of those younger people who came within their sphere of influence principles of the highest morality as well as instruction in the best and most efficient methods of carrying out their work. We cannot forget those old teachers who built into many of us all that we know, and who gave us a chance in life which we have been fortunate enough to work out. But I have got to go beyond that to-day. Since the war finished science has taken hold of the forces of the world in a way that was never thought of before. Every element which contributes to the good of man is being thoroughly analysed. To-day science has a freer hand than it has ever had before in the history of the world, the object being that it shall harness the forces of the world for the good of man without entailing the necessity for any extra human energy. That is the basis, and the only basis, upon which the standard of the life of man can be raised. We have a great outcry in these days that the standard of life must be on such and such a plane, according to the point of view of the man expressing the view; but it is a truism that we can only divide what is produced by the world among the

people of the world. In every seven years, as of old, what is produced in the world is pretty well spread out over the human race, and there is very little left, except in static form, of what was produced seven years before. If we can harness the forces of the world—and we can only do it by the development of the application of scientific principles—then we can raise the standard of life by one of two things. We can either use more commodities ourselves or we can have more leisure. We can make our choice; we cannot have both. So far as I am concerned, I am not really a believer in giving men too much time to play in, unless we have taught them how to use that time for the good of themselves and for the good of humanity at large. First of all, I think we have a need for a common language in order that scientific documents and writings of every description may be intelligible to all who are acquainted with that common language. Many words are now used for scientific purposes which cannot be found in any dictionary, and are therefore unintelligible to the people at large. A common language establishes a common means of transmitting knowledge. The Arabians discussed the motion of the celestial bodies and the doctrine of attraction, but the idea died away until Newton, without knowledge of the Arabic author, made the discoveries in which he had probably been preceded. The Chinese have been working out their celestial compilations, for anything we know, since the Deluge, but the world at large has received no benefit from their work. It is to men like Fust or Coste, who were impelled by the burst of intellectual progress to devise means for the better diffusing of the knowledge already among men, that we acknowledge our debt. The main idea, as far as I can see, that the Textile Institute has to put forward is to vivify the intellectual inertia which lies all around us, and we cannot do it unless we have a language which is understood by all of us. We have a mass of intellect and capacity which is untouched. We have just a few men—not very many—applying themselves to pure science. We do not need a great number of them, but we need the best, and we want the best that they can produce to be at the disposal of all. That is my idea how progress shall be effected. I really believe that the vast majority of people want this scientific pressure to be brought to bear upon them. They certainly will if they can see that an advantage will accrue. I am afraid, however, that there has not been that liaison hitherto between what you may call the education authorities and the ordinary workman which the Textile Institute can bring about, and which ought to be brought about if the status of the Institute is to be properly maintained. I think we can devote ourselves very largely to that end. I think that every technological institution should not merely keep a record of the name, age, and address of the pupil, but should let the employer know the state of proficiency reached by him. All our standard wage systems governing the trade have one defect—that we cannot, without creating trouble, specially remunerate a boy who gives special service. Most of us have heard the phrase that "It is the hope of reward that sweetens labour." We want to teach a boy that by going to the Technical School he will ease his work because he can use his brains and save his body; that he will be able to cut out all sorts of faulty work, and that his production will be in greater quantity as well as of better quality. If the employer could be permitted to recognise that particular extra service, I am quite sure we shall get a burst of enthusiasm for technical knowledge which has hitherto not distinguished the textile industry. I want a student to know for what purpose he is shaping a particular thread. I want his interest to be aroused concerning the object of the work he is doing. I do not know that I want to say very much more with regard to what we should do during the next twelve months. To my own mind the ideas to which I have given expression provide ample opportunity for the exercise of all our wits and wisdom. I have preferred to go on a line that I could carry through, rather than grab at the stars and fail at getting anything. Definitely stated, my view is that this Institute should provide the liaison between the highest research institutions, our technical colleges, and the

ordinary working lad at the very bottom of the tree. We could then, I think, feel quite assured that out of the rut we should get a very great number of young men who would attach themselves to this Institution and seek to develop themselves very much further than what at the present time they seem to be capable of doing. Mr. Emsley is an optimist, and so am I; but I am quite sure of this, that unless we prove ourselves capable of leading the world our textile trades will cease to exist. The history of the world is replete with examples which are best illustrated by the old Grecian tale of the torch, in which the human species engages in a race of intellectual progress in which the bearers of the torch hand it from one to another as they become exhausted, but no one is allowed to take up the torch until he is in the flower of youth, and must hand it on to his next neighbour as soon as age or accident has weakened his frame or retarded his pace. He falls back and dies; his neighbour carries along the torch until he, tco, hands it to another. The torch then, which is humanity, the onward progress of mankind's improvement, whatever may be the goal to which it must ultimately come, has advanced without any perceptible tendency to retrograde movement, while the bearers of the torch, the nations of the world, have fallen away and died when their part in the race of human advancement has been played. As it is with nations, so it is with communities. Unless we can continually run in wider and wider circles, and carry the torch with greater firmness and greater efficiency than can be done by the youth and manhood of other nations, we shall lose the premier position that we hold to-day. If we maintain our premier position, then we shall be able to hand on to our sons the magnificent heritage we received from our forefathers, not merely untarnished but blessed, because we have carried the torch.

ELECTION OF VICE-PRESIDENTS

The General Secretary stated that there were three Vice-Presidential vacancies and that only three nominations had been received. Therefore the gentlemen nominated automatically became elected. Messrs. John Crompton (the present Chairman of the Council), Mr. J. H. Lester, and Mr. Henry P. Greg were thereupon duly elected as Vice-Presidents of the Institute.

ELECTION OF THE COUNCIL: RESULT OF BALLOT

The General Secretary stated that the election of the members of the Council had taken place by ballot. He produced the certificate of the scrutineers of the ballot papers, and in the result the following gentlemen had been elected to fill 10 vacancies—Messrs. T. Fletcher Robinson (Manchester), H. Binns (Bradford), F. Wright (Bolton), E. B. Fry (London), W. E. Baker (Manchester), H. Richardson (Bradford), A. Pollitt (Manchester), E. E. Cockcroft (Luddendenfoot), C. S. Ickringill (Silsden), W. W. L. Lishman (Todmorden).

Mr. C. S. Ickringill moved, and Mr. W. Bailey seconded, that Messrs. Arthur E. Piggott, Son & Co. be reappointed Auditors, and the motion was carried unanimously.

The General Secretary then read the first list of members of the Institute who had been elected Fellows and Associates, as printed in the April issue of this *Journal*.

Mr. William Frost proposed that a cordial vote of thanks be accorded to the staff of the Institute for the excellent manner in which they had discharged their onerous duties. The work had been very arduous, not only for the general staff but also for the staff of the *Journal*, and it was only fitting that their services should be properly appreciated.

Mr. T. Fletcher Robinson seconded. It would very readily be understood that as Treasurer of the Institute it was his privilege and pleasure to come in very close contact with the staff, and he could fully endorse the remarks made by Mr. Frost in regard to the excellent manner in which they had discharged

their responsibilities. The greatest possible harmony and enthusiasm prevailed among the staff, and they were striving in every possible way they could to further the interests of the Institute.

Mr. John Emsley, J.P., supported the motion. Like Mr. Robinson, he had also been in close personal contact with the staff, and, without their cordial co-operation and assistance, it would most certainly not have been possible for him to have done the amount of work he had accomplished. In addition, he would also like to thank from the bottom of his heart all those gentlemen who had spent so much time and showed so much patience in the gaining of the Charter. It had been a work of love, purely and simply. Mere monetary remuneration would never have induced those gentlemen to go to the trouble they did.

The President then put the vote of thanks to the meeting, and it was carried unanimously.

The meeting closed with a vote of thanks to the President.

London Section

Meeting at the Clothworkers' Hall, Mincing Lane, London, 15th March 1926, Mr. F. H. D. Haggard presiding.

RAW WOOL: THE ECONOMIC POSITION

The Chairman, after introducing the Lecturer, Mr. Eldred Hitchcock, C.B.E., thanked Mr. S. M. Townsend, the Master of the Clothworkers' Company, who was present, for the kindness of the Company in lending their hall to the London Section for their public lectures during the winter. Illustrating the benevolence of the Clothworkers' Company to the textile industry, he mentioned that they had given nearly £250,000 in all towards the establishment and maintenance of textile departments at Leeds University.

Mr. Eldred Hitchcock said the economic position of wool, which is measured by price, depends ultimately, like every other commodity, upon supply and demand. The supply and the demand are, however, very wide apart, and many processes and financial transactions take place before the wool in its finished form becomes available to the ultimate consumer—the public. At least a year, and more often longer, elapses between the marketing of the raw wool and the sale to the consumer of the clothes or other articles made from it. The factors which ultimately govern demand are very complex and far removed from those which govern production. Dealing with the question of wool production, the lecturer said raw wool is not a straight article like cotton or steel, and its standardisation (e.g., as cotton is standardised for the purpose of dealing in futures) has not been found in general to be a practical proposition. Statistics of wool production are therefore subject to factors which are not constant owing to the varying nature and condition of the raw material itself, and estimates of production in terms of actual fibre content are at the best rough estimates only. The wool production of the world, especially in the main exporting countries, is fairly accurately known, and the figures can be sufficiently well interpreted by the trade for all practical purposes. Certainly wool production estimates are less difficult to make than are those of the yearly cotton crop. Wool production statistics, unsatisfactory as they may be, need not bother us. The incalculable factor is that of consumption owing not only to the difficulty of collecting the statistics of spindle consumption in each country, but to enormous variations possible in consumption in the spinning of different counts of yarns and to the extent to which substitutes can take the place of virgin wool. Price and fashion react in a wholly incalculable manner upon the weight of new wool passing during any given period through machinery. When to these factors is added that of the machinery capacity employed, it will be readily understood

why estimates of consumption, with the best will in the world to obtain accuracy, can contain margins of error and of difference amounting to 100%. The questions to be foreseen are many, and include—(1) What proportion of the total machine capacity will be working? (2) If this figure be arrived at, what consumption of raw material will this involve? (3) What proportion of new wool will this raw material contain? (4) What effect will change in fashion have upon the counts of yarns required or upon the yardage of cloth necessary? (5) What reaction will fluctuations in price have upon the rate of consumption?

To these questions no one person or committee is clever enough to furnish an answer where the margin of error may not be stupendous. In practice a great number of opinions, arrived at in a variety of ways, for many and diverse reasons, will at least cancel out amongst themselves the more extreme views. In my view the greatest danger is to be feared from any central statistical bureau which attempts to estimate the position at any given time on behalf of traders in general. I have personally had some experience of such methods, and I think it will be found that all the evidence on the subject shows that any central statistical machinery is just as likely—and in fact more likely—to be wrong as right. The method of trial and error on the part of a great number of intelligent units with knowledge of the business will approximate to a net result nearer the truth than any central statistical bureau that can be devised. Having somewhat dogmatically, perhaps, taken up that position I do not wish to suggest that nothing can be done, or that the present position of the statistical data of the trade is satisfactory. What I wish to indicate are its limitations and the very great reserve with which all statistical data must be utilised. I remember Sir Arthur Goldfinch saying some years ago that, after all, "inferential statistics" were the only wool statistics worth while. There was much wisdom in that remark, and I would add that the greater the number of individuals with knowledge of the business who make the inferences, the nearer we are likely to get to the truth of the matter. The whole art of wool statistics is the art of interpretation based on knowledge, and it does not lend itself to any great degree of scientific treatment. But that assumes at least that some attempt is made first to collect what evidence in the form of systematic statistics can be made available, and secondly that members of the wool trade throughout the world will seriously interest themselves in the subject, even if only to the extent of appreciating the serious limitations to which all statistical data, and especially that of the wool trade, is subject. The more information obtained the better, so long as we do not exaggerate its practical value. In any case statistics rapidly become out of date, and a rapid approximate statement is almost always of greater value than a delayed statement, however complete. Having said that, there are certain broad facts to which attention should be directed. Firstly, it is clear that taking the Western and Eastern World together, there is, over a period of years, a definite and steady increase in the demand for clothing and other goods made from wool or in which wool at any rate forms a part, and at the same time the spindle capacity of the world is also steadily increasing, and it is just as clear that the sheep population of the world, and even the wool yield of their fleeces, is not increasing in the same proportion. Secondly, it is also true that not more than a certain proportion of the total purchasing power of the populations of the world is available for the purchase of clothes, and especially of woollen clothes. Price plays an undiminished, and, in fact, increasingly important factor in determining the volume of clothes bought, and so long as the price of clothes is above the general level of prices and of the cost of living, so long will consumption of clothes and of wool be restricted. The lecturer said he left out of account somewhat exceptional, though by no means unimportant, factors, such as the relative decline in textile purchases by a population such as that of the U.S. resulting from the increase in the distribution of purchasing power on such articles as motor cars. That is a phenomenon which was rarely alluded to in works on economics. We must consider, he continued, the effect of price

on wool demand. Meanwhile, it is convenient to compare to-day's with the pre-war price of wool, although it was not necessarily suggested that what was right pre-war should obtain now, but it was at any rate a useful basis for comparison. Where before the war the great wool exporting countries—comprising roughly two-thirds the British Empire and one-third South America—received from the great importing countries—mainly England, France, and Germany—at most about £50,000,000 for their wool in a good year, the price level to which wool had climbed by December 1924, was approximately £150,000,000. In the economic position of the world at that time the extra £100,000,000 for raw wool was obviously a figure at which the wool could not be absorbed. I say "obviously" for in the previous July I had published an article pointing out what seemed at the time to be this very elementary truth. The misinterpretation of the statistical position, and the neglect by the great majority of individual members of the trade of any serious consideration of the position, and the tendency to follow a lead, produced a psychology under which any price level would have seemed a perfectly natural and justifiable one, until the hard facts of ultimate supply and demand reversed the whole position with a bump. Happily the position to-day is on a sound basis, and wool can be bought on an average at little more than 50% over the pre-war figure, or, say, £75,000,000, for the clips. In relation to the general level of wholesale prices, that is a sound and even favourable position. Unfortunately, however, that is not the whole of the story, for after all the ultimate consumer upon whose purchases everybody depends, does not buy raw wool, or even tops or yarns or cloth. He or she buys clothes, and so far as can be ascertained, quality for quality, clothes are still at least double the pre-war price. It will be pointed out that this is due to perfectly good reasons—higher rents, shorter hours, lower production, higher wages, rates, taxation, legal enactments and administrative efficiency, to say nothing of the high cost of cotton. I can only agree, and at the same time point out that the net result is less business, higher costs, and restricted consumption. I often hear friends of mine talk of the high profits and prosperous condition of the wool textile industry. I hope that is so in some cases, but when I ask for the particular cases, I am generally referred to the published balance sheets of some association of commission firms engaged on subsidiary processes of dyeing, combing, and so on, or to the almost fabulous profits of the retail stores, who generally add to their cost price from the manufacturer or the merchant a margin equal or even greater than the combined amounts received by the grower, the financier, the shipping company, the wool merchant, the comber, the dyer, the spinner, and the manufacturer of the cloth. I don't say that there are not perfectly good explanations, but it is quite clear that the great textile manufacturing industry of this country and the wool production industry of the Empire, are both restricted in their market as a result of the high prices which the public is asked to pay for clothing, prices very much above the general level of prices and the cost of living. For years past manufacturers' capital has been oozing away, and even to-day, when trade portents are brighter, in most parts of the country not more than 50% to 60% of the capacity of the looms are unemployed. This state of affairs is a definite tax upon production and upon the wealth of the country—its maintenance restricts business not only within the countries of Great Britain, but by increasing costs reduces our export trade. Over half the value of all our exports of manufactured goods, even including coal, consists of textile goods, and it is therefore by far and away our most important industry. Certainly conditions are becoming better, but in spite of retailers' lavish display and their advertising appeals which are all to the good, trade will not recover till retail charges are lowered. We have, of course, to remember what I mentioned at the outset of these remarks, viz., that supply and demand were often far apart, and it may be that the retail trade is in part absorbing some of the indiscretions of the raw wool trade of eighteen months ago. I don't for a moment set out to teach anyone his business, and

I do not apply my remarks to private trade alone. Government services still charge extravagantly, and co-operative shops are just as relatively expensive. It may be that the remuneration of labour, of capital, and other services in the later stages of production and distribution before the war was too low. I can, however, only point out the relative discrepancy in price levels and the inevitable restriction of sales and of business which follows. The public in many respects may have lost its sense of discrimination, of quality, and of values, but gradually and surely prudence and care in purchasing is returning, and the more that is encouraged, and cheapness and abundance stimulates trade, the greater will be the demand upon our Imperial resources of wool production with reciprocal Imperial trade, without which the trade and prosperity of this country cannot revive, or its people be employed. If we can only overcome some of the difficulties to which I have referred the wool textile trades will boom. They are at present on a perfectly sound basis, and in spite of a temporary reduction of world machine consumption to almost 50%, price is steady and large quantities of wool are being absorbed. The universal financial stringency has been a saviour in disguise, for by it high prices and undue speculation have been checked. There is a large and expanding world consumption to be met, but the point is, it can only be met at a price. In my view, any appreciable increase in wool values will restrict business to an extent which will damage the trade. Wool values are not on a very reasonable level, and it only needs the position of the raw material to be translated to the finished article available to the public for a steady increase in business to result. The great difficulty which will then emerge will be the insufficiency of wool production. It sounds strange to say that to-day, but that will clearly become the position. In this connection we have happily an enormous volume of substitutes, from torn-up woollen clothing to the latest vegetable fibre masquerading as wool. No fibre at present on the market can remotely give the essential qualities possessed by new wool. But they are all useful, and will be increasingly wanted both for making the cloth production required possible, and also for serving as a governor for the maintenance of reasonable price. Change in women's clothes, both as to quantity and the materials from which they are made, have greatly reduced the amount of wool required, but this is more than offset by the world increase in demand, especially in the countries of the Far East. Since the war there has never been a time when the economic position of wool was sounder than it is to-day. Price fluctuation resulting from the natural operation of supply and demand is the only automatic governor on the process of production and distribution. Instead of rushing supplies forward during a part of the season available, supplies are now allocated over a series of auctions throughout the season. In this respect Australia has followed London, and, if I may say so, improved on the model. In addition to this loose control suggestions of various kinds have been made for increasing such restrictions with the object of flattening out cyclical fluctuations in price, and with the experience of B.A.W.R.A. in mind, and especially of the high prices which wool fetched during the period of that control, these various proposals have culminated in the suggestions sponsored by Sir John Higgins for a stabilisation scheme for Australian wool on which I should like to say a word as to its general bearing. I think in this connection we should remember that wool is an article of common everyday consumption by the masses of the population, and that any formal attempt especially by Governments, having even the appearance of forcing up prices, is likely to lead to international complications and retaliation, such as American retaliation on cotton. In these matters therefore one country does not stand alone, and especially does this apply to countries within the British Empire. The operation of such proposals might well result in serious economic as well as political difficulties, which it is our business at least to foresee well in advance. If Australia says that in any given season her wool growers shall not receive less than the fair cost, including

a reasonable return for growing wool, and that I think is the basis of the proposals, she is perfectly entitled to take what means she thinks fit to achieve this end. What she cannot do, without great harm to her ultimate interests and to those of the rest of the world, is to force a level of prices which the general public cannot or will not afford to pay. She will merely restrict her market and drive demand either to substitutes or to other competing producing centres. What I suggest would meet the very legitimate case of the grower is a scheme run and controlled by growers themselves for insuring their own risks by the setting up of a central reserve or pool contributed to in good times by a levy per bale of wool exported or sold, the amount of the levy varying with the level of wool prices. If such a central fund could be built up—and the period of good prices upon which we can in all probability depend for some time ahead would make the present a good time in which to start it, provision could be made for meeting the margin necessary in really bad times, without courting antagonism from other interests concerned or other Governments. Australia is entitled to make whatever arrangements she likes for her own security. A very fair share of the burden for ensuring Imperial security by means of the Navy is in fact largely borne by this country, and to augment this tax by increasing the price of the raw material, upon the cheapness of which our ability to meet the cost depends, is not, I think, to the best interests of the Empire. During the period of the war and for some time afterwards that burden was a very great one to this country. Here I would like to interpolate a little history. It is generally assumed that the Imperial Wool Purchase which was arranged in September, 1915, was arranged mainly on the initiative of the British Government in order to ensure military supplies. It is quite true that was the position, placed some little time before that, before the representatives of Australia and New Zealand by Lord Derby, who was then Minister for War. But his proposal applied to crossbred wool alone, i.e., to not more than 15% of the Australian clip, and practically the whole of the New Zealand production. That proposal had, however, for certain reasons been dropped, and it was not till some time later that the matter was taken up by cable by Mr. Hughes on behalf of Australia with Mr. Bonar Law, who was then at the Colonial Office. In view of the increasing possibility of the diversion of a large part of the mercantile marine from the long Australian route to the short Atlantic one, of the growing intensity of the submarine campaign, and to the possibility of the need for bringing over an American army and supplies to Europe, Mr. Hughes regarded with apprehension the possibility of unshipped and unmarketable Australian wool and other products accumulating at her ports, imperilling the whole financial future of that great Commonwealth. Under such conditions his tenure as Prime Minister—and I mean this in no bad sense—would have been unstable, and the important political issues with which he was then faced would have been lost. He therefore cabled to Mr. Bonar Law urging on these grounds that the Imperial Government should agree to purchase all Australian wool and to pay for it whether it was shipped or not. As it turned out the purchase proved eventually to be good business for both Governments to the extent of £60,000,000, and Australian growers had never known more prosperous times than they experienced under the scheme and that of B.A.W.R.A., which was an extension under another name. That was a great experiment made to meet exceptional and unprecedented circumstances, but it does not provide an analogy for meeting the entirely different conditions of to-day.

The Chairman said, as the representative of a firm in close touch with Australian interests, that he could find no holes to pick in Mr. Hitchcock's paper, which he thought contained many extremely valuable suggestions. He personally agreed with Mr. Hitchcock on every point, and would like to congratulate him on his extremely interesting paper. He proposed a vote of thanks to the lecturer, and this was carried with applause.

COMMUNICATION

To the Editor

Dear Sir,—There is a matter which calls for comment in the excellent paper of Clibbens and Geake on "The Absorption of Methylene Blue from Buffered Solutions." On page T148 they state—" . . . the absorbing hydrocelluloses contained sulphuric acid in some *unknown combination* (italics mine) which could not be broken down by boiling with dilute alkalies," and again on page T166, " . . . the conclusion appears unavoidable that acid is consumed in reactions other than true hydrocellulose formation." Quite so. There is formed a cellulose sulphuric ester (cellulose hydrogen sulphate) exactly analogous in reactions to ethyl hydrogen sulphate, in regard to stability to acids and alkalies. Boiling with caustic alkali simply forms an alkali salt which is quite stable to alkali.

The sulphuric ester may be decomposed either by boiling with alcohol according to the scheme—

$$R.O.SO_3H + Et.OH = R.OH + Et.O.SO_3H$$

or by hydrolysis at the boil with dilute acids.

Cellulose sulphuric ester is encountered in both the nitrate and acetate industries when sulphuric acid is used as catalyst. For example, in cellulose acetate as much as 1% sulphuric acid may be combined during the course of manufacture, and is only removed by acid hydrolysis.

It is therefore erroneous to imply that the mode of combination of the sulphuric acid in the case before us is *unknown.*

Yours faithfully,

56 Oxford Street, Manchester. (Signed) FREDK. C. WOOD, M.Sc., F.I.C.

NOTES AND NOTICES

Annual Conference Cancellation

Although this note may not actually reach members prior to the dates selected for the Institute's Annual Conference, it may be useful to record the circumstances under which the decision to cancel the Conference was reached. The matter was discussed with the President (Mr. Wm. Howarth J.P.), and it was felt, even so early as the 6th May, that the whole situation was doubtful. It was decided to call an immediate meeting of the Committee in charge of the Buxton Conference arrangements. Having regard to the necessarily small response to the invitation and attendance form issued, it was agreed that even in the event of an early cessation of the general strike the complications of the situation would militate against a really satisfactory attendance. It was resolved therefore to cancel the Conference forthwith. The General Secretary telephoned several officers of the Institute, and found that the suggested cancellation was commonly regarded as desirable. The Committee referred to also agreed that the meeting of Council for May (19th May) should not be called. The question of holding the Conference at a later date was referred to next Council meeting, which was expected to take place on the third Wednesday in June. After the decision to cancel the Conference, members who had notified attendance were communicated with direct, whilst the British Broadcasting Company kindly announced the cancellation by wireless.

Membership of Institute and Description

Prior to the obtaining of the Royal Charter of Incorporation, a tendency on the part of a very limited number of members of the Institute to use abbreviations after their names—"M.Text.I." or "M.Text.Inst." for instance—was noted. The official attitude in regard to the practice varied from time to time,

but generally the attitude may now be best described, perhaps, as having been one of toleration. Now that facilities exist, by virtue of the provisions of the Charter, for the securing of Diplomas of qualification in textile technology in connection with membership of the Institute, the use of abbreviations other than A.T.I. or F.T.I. is definitely forbidden. Several instances have already arisen in which it has been found necessary to request discontinuance of the use of abbreviations to indicate merely ordinary membership of the Institute. The only form of description of ordinary membership which can now be permitted is the addition to the name of the description, in full, "Member of the Textile Institute." No abbreviation is allowable other than the abbreviations associated with the Diplomas of the Institute, and members who have previously used abbreviations in connection with ordinary membership should note carefully the demand for discontinuance.

SHACKLETON, George (Bradford).
TINDALL, Arthur Richard (Bradford).
WINDLE, Joseph (Nelson).
WOODHEAD, Arthur (Shipley).

Elected to Institute Membership

At the April meeting of the Council, the following were elected to membership of the Institute—Norman Booth (Textile Teacher), 46 Greenhead Lane, Dalton, Huddersfield; Vasudeo Bose (Carder and Spinner), 70 Cantonments, Bareilly, U.P. India; Bertram Cheetham (Weaving Student), "Coniston," Cote Green, Ludworth, near Stockport; William B. Elliot (Tweed Designer), 5 Ann Street, Tillicoultry, Scotland; George S. Ferrier (Research Chemist), 10 Hamilton Park Terrace, Hillhead, Glasgow; Percy H. Gee (Textile Teacher), 15 Springwood Street, Huddersfield; James Greenwood (Teacher of Textile Design and Colour), 78 Chatburn Road, Clitheroe; William A. Grocott (Power Loom Overlooker and Lecturer), 33 Yarborough Street, Pendleton; Harald Hygrell (Manager of Spinning and Weaving), Karlshamn, Sweden; G. N. K. Iyer (Mill Manager), c/o N. B. Vyas, Esq., Headmaster, Weaving School, Bulsar (*via* Bombay), India; James A. Lord (Textile Student), 196 Walmersley Road, Bury; D. N. R. McEwan (Chief Chemist), c/o Wolsey, Limited, Abbey Meadow Mills, Leicester; Frank W. Oldham (Cotton Mill Manager), 2 Holly Grove, Hollins Lane, Accrington; John S. Pearson (Assistant Mill Manager), c/o Mr. F. Wilson, 215 Drake Street, Rochdale; John B. Percival (Chartered Patent Agent), 20-22 St. Ann's Square, Manchester; Arthur Riley (Manufacturers' Clerk and Textile Student), 11 Eldon Road, Edgeley, Stockport; Herbert T. Rothwell (Textile Teacher), 35 Dalton Green Lane, Dalton, Huddersfield; Ralph P. Richardson (Spinning Master), Technological Research Laboratory, King's Circle, Matunga, Bombay, India; Charles W. Schoffstall, 1474 Columbia Road, N.W., Apt. 410, Washington D.C., U.S.A.; Robert Sewell (Manager, Broadstone Mills, Reddish), 286 Wellington Road North, Heaton Chapel, near Stockport; W. Farrar Vickers

(Oil Refiner and Manufacturer), Gascoigne Street, Boar Lane, Leeds; Harold A. Wilkinson (Assistant, Cotton Section), Messrs. Begg Sutherland & Co., Ltd., Cawnpore, India; Leonard Wilkinson (Instructor in Weaving), 17 Melford Street, Dudley Hill, Bradford; Thomas S. Wilson (Bobbin Manufacturer), c/o Wilson Bros. Bobbin Co. Ltd., Cornholme Works, Garston, Liverpool.

GENERAL ITEMS AND REPORTS

Proposed International Wool Federation

M. Maurice Dubrulle, in giving an address before the Bradford Textile Society on Monday, 1st March (Mr. Sydney E. Illingworth presiding), entitled "International Co-operation in Relation to Wool Production and Consumption," said that the wool growers' conferences inaugurated by the Bradford Chamber of Commerce had proved most fertile in the cultivation of a desirable co-operation between all those engaged in the production and distribution of the raw material, and the foundations for international co-operation had been laid by the recent arbitration agreement between England, France, Belgium, and Germany. Amongst matters calling for international action were the questions of wool supplies, of packing of wool, statistics of consumption, interchange of technical knowledge, and of business credits. Another line of action was the influencing of fashion. Whereas a few years ago at least four yards of material were required for a lady's garment, in these days two yards were more than sufficient. A change of fashion with a view to providing more employment for machinery could only be achieved by a world campaign conducted at one and the same time, and mainly from the large capitals such as London, New York, Paris and Berlin. With regard to the question of how co-operation could be effected, M. Dubrulle said he was convinced that success could only be achieved by a proper co-ordination of many individual and partial endeavours into one vast international organisation which would comprise representatives from every country for the collation, investigation, and resolution of the many questions in which they were all equally interested. In advancing a concrete suggestion, he would propose that an International Wool Federation should be the basis of this endeavour. He could imagine that its functions would be delegated to three important committees—firstly, a committee to further technical co-operation to deal with wool supplies, sheep-breeding, and wool packing, &c. A statistical bureau could also be organised by this department to receive from each national branch of the Federation periodical statistics of wool consumption and production. Secondly, a committee to further technical co-operation, which would be aided by a central research laboratory where the examination and classification of all discoveries or improvements of recognised value to the worsted and woollen trade would be undertaken. Thirdly, a committee to further commercial co-operation in respect to fashions, credits, &c.

Mr. Douglas Hamilton said he hoped Mr. Dubrulle's challenge would be taken up in the spirit in which it was made. He found himself in almost entire agreement with the points raised by Mr. Dubrulle, and stressed the desirability of having reliable statistics.

Col. F. Vernon Willey said he had been impressed by the fact that the world's textile consumption, reckoned as a portion of its budget expenditure, was less than it was before the war. That was a very serious matter both for employers and employed, and it was an outstanding reason for international collaboration. Clearly the present degree of consumption was not going to employ the wool textile machinery of the world. With regard to statistics, he was an unrepentant believer in more attention being given to them. He hoped the wool textile trade would see the wisdom of the movement, if only to refute the charge of inefficiency which was being levelled at the employing class by the workers. In his view the slumps of 1920 and 1925 would have been corrected by adequate statistics. In 1920, had statistics existed, it would have been obvious that it was impossible to pass the volume of wool then existing through the spindles of the world, and therefore, inevitably, prices must have fallen. In 1925 it would have been seen that the forecasts were based upon a continued operation of machinery at the

then existing rate, but that in view of the resources of the trade and the purchasing capacity of the world, it was impossible to pass the amount of wool existing through machinery at its then level of prices, because those prices were out of proportion to the general level of prices as shown in index figures. Statistics did not exist (or were disregarded) to justify either of those two deductions, and he suggested that accurate statistical information would have enabled the trade absolutely to avoid slumps such as the two dramatic slumps of the past six years.

Wool Problems

Mr. Harry Dawson, dealing with "Some Existing Wool Problems" before the Bradford Textile Society on Monday, 15th March (Mr. Sydney E. Illingworth presiding), said that three factors were seriously affecting the wool position to-day. These were (1) finance, (2) fashions, and (3) substitutes. With regard to the first, as a result of the slump in prices in 1925, the financial capacity of the textile industry of the world was probably weaker than for many years. For the first time in fifteen or eighteen months, however, he felt a little more optimistic, and was convinced the worst was over. There was an utter absence of speculative dealing, and because of that prices were more set and on a sound basis. From any point of view—the economic or the commercial—prices were now on a reasonable level, and for the first time in two years trade could be done without a loss by turning wool into semi- or fully-manufactured articles. Another hopeful factor was that home traders were beginning to enjoy an advantage over their Continental competitors owing to the return to the gold standard.

The second factor was that of fashion or preference, which was found in the abnormally strong demand for fine worsteds in preference to cheaper woollens or the coarser crossbred cloths. That was a healthy reaction. Worsted cloths had been in very slack demand for two or three years, owing to the price of wool and the more expensive costs of production. But with good 64's top available at about the four shilling basis, fine worsteds could be produced at a reasonable cost, and reports from every market during the past few weeks had shown a wonderful demand for fine worsteds, and especially for fancy worsteds. This preference had had an immediate effect on the wool market in the finest merinos, and especially 70's. Despite financial tightness and a world-wide bear movement, it was remarkable how steady merinos were keeping in value. Crossbreds, he thought, would take care of themselves. All the wool in the world was wanted. Crossbreds, though neglected to-day, were cheap, and would create a demand.

With regard to the third factor—adulterants and substitutes—the wonderful development of the artificial silk trade had doubtless its effect on the consumption of wool, especially in the United States. Many estimates had been made, and he did not want to take an exaggerated one, but a moderate and conservative estimate made by men having the confidence of statisticians placed the amount of raw wool that had been displaced during the past year at from 600,000 to 800,000 bales.

In the course of the discussion, Mr. H. Kenningham said one curious feature was that despite the poverty of the Continental nations they could go on financing purchases in London and the Colonies, and only at the present London sales they had seen wools go to the Continent at prices which were almost equivalent to the price of the top in Bradford. He would like to ask Mr. Dawson how far the infusion of artificial silk would help to regulate the price of the natural wool.

Mr. Arthur Bentley said the statistics of shipments from the Colonies were given in bales, but sometimes the yield of wool per sheep would be a few ounces different from the yield in the previous season, and that made a great difference to the quantity of wool available.

Mr. Dawson said if the production of artificial silk increased it would have a sobering effect on wool consumption and therefore on prices. With regard to shipments from the Colonies, these were very reliable. The weight per fleece varied, but the weight per bale was practically constant at somewhere near $3\frac{1}{2}$ cwts., because that was the limit of weight laid down by the London Dock authorities.

M.

THE JOURNAL OF THE TEXTILE INSTITUTE

Vol. XVII JUNE 1926 No. 6

PROCEEDINGS

NOTES AND NOTICES

Textile Institute for the United States

American textile journals which reached this country in the early days of June contained references to a proposal for the establishment of a new organisation described as a Textile Institute for the U.S.A. The project was announced at the annual conference of the American Cotton Manufacturers' Association held at Atlanta, Ga. The scheme is of more than passing interest to this country and probably to several other countries concerned with the textile industries. The Textile Institute of Great Britain and Northern Ireland was founded in 1910 and in its early years played an important part in promoting co-operative research. In fact, the Institute itself embarked upon more than one useful research scheme. Now, since the formation of a Government Department of Scientific and Industrial Research and the four Textile Research Associations, the foremost functions of the Textile Institute in the direction of increasing the store of knowledge are the provision of a platform for the discussion of technological and scientific problems and a suitable medium for the publication of scientific and technical literature. The Institute's Royal Charter—granted a year ago—has imposed further obligations on the Institute, those of raising the status of those who profess or practice Textile Technology, and of providing an examining body in connection therewith. The Institute, being empowered to confer post-graduate diplomas (in the form of Fellowships and Associateships) to members who satisfy its examining authority, will be expected, also, to take an active part in all future discussions on the training of textile technologists. Further, the requirements in regard to the publication activities of the Institute may be expected to expand. The records of original work on the part of candidates for diplomas will invariably receive special consideration by the examining body. In consequence, a distinct stimulus to publication is exerted, and such stimulus is already reflected in a heavy increase in the number of papers submitted to the Institute's *Journal*. It will be interesting, therefore, to compare with the above outline of this Institute's functions, the scope of the scheme for a Textile Institute in the U.S.A. Here are the proposals, as tersely summarised in the *Textile World* (U.S.A.) of the 22nd May—

The skeleton plan for a Cotton Textile Institute proposed by George S. Harris at the A.C.M.A. meeting in Atlanta, is as follows—

Organisation

Board of Directors.
Director General.
Chief Statistician.
Technical Experts as required.
Converter (representing Converters' Association),

Wholesaler (representing Wholesale Dry Goods Association).
Retailer (representing Retail Dry Goods Association).
Legal Directors.

Functions

Secure, tabulate, and distribute data covering all phases of industry and commerce affecting cotton textiles.
Check and advise entire industry and trade.
Publish periodically price index by construction groups including all yarns.
Conduct group advertising at home and abroad.
Conduct research relating to extension of use of cotton textiles.
Direct group activities in export trade.
Direct in all legislation affecting cotton textiles.
Direct as to trade customs, settlement of disputes, &c.
Co-ordinate work of existing association.

Although limited to cotton, the project obviously covers a vast field, and in calling attention to the wide scope and variety of the activities contemplated our object is not to offer criticism thereon. Nevertheless, the suggestion may be ventured that the selection of the title of "Textile Institute" for an organisation so widely different in its conception from our own Textile Institute, is possibly unfortunate, and may lead to some confusion. Our own Institute is recognised in all textile countries for its special interest in a particular field of activity, and already has Fellows in America. Though the numbers of such members may be few, the interest in our monthly *Journal* extends considerably beyond the membership circle, as is shown not only by the increasing number of U.S.A. subscribers but by the extensive quotation and often complete republication of matter from our pages in American textile periodicals. The possibility of a Textile Institute for the U.S.A. raises the hope, at any rate, that, in the not too distant future, publication of scientific textile literature in America may be associated with mutual exchange facilities in relation to the output in this country.

The Council of the Institute

At the meeting of the Council on Wednesday, 16th June, the newly-elected President (Wm. Howarth Esq. J.P.) occupied the chair at the outset, pending the election of chairman. Mr. John Crompton was unanimously re-elected to the chair, whilst Mr. T. Holdsworth was reappointed vice-chairman. Other elections were in contemplation, including the various committees, but in this instance it was decided that the chairmen of the respective committees should meet at an early date and make recommendations for the next meeting. The Hon. Secretary (Mr. W. Frost) and the Hon. Treasurer (Mr. T. Fletcher Robinson) were unanimously reappointed. The General Secretary called attention to the fact that owing to elevations to vice-presidency and to one resignation—that of of Dr. W. L. Balls—five vacancies had arisen in council membership. It was decided to refer to the recent ballot in connection with the annual election of the Council, and it was agreed that the first five who did not then secure seats be now elected. Accordingly, Messrs. W. Wilkinson (Blackburn), E. Midgley (Bradford), A. B. Shearer (Manchester), S. Watson (Hyde), and W. Kershaw (Manchester), were declared elected. With regard to the Yorkshire Section and the London Section Committees, the nominations of the Sections were approved and the lists of names of these committees appear on another page of this issue.

Delay of the Institute Annual Conference

Although considerable regret was expressed on account of the necessity which had arisen for the postponement of the Institute's Annual Conference, which should have taken place at Buxton during Whit-week, yet it was felt to be

inadvisable under present conditions to consider anything like immediate re-arrangement of the event. It was agreed, therefore, that the question of date of the fixture be placed upon the agenda for next meeting. The general opinion of the Council appeared to be that October would be the most advantageous time at which the Conference might take place. The hope was definitely expressed that the two important papers announced for the postponed Buxton Conference would be still available, whilst Mr. W. Frost found general acceptance for his suggestion that the venue for the fixture should remain as previously—Buxton. In considering the whole matter, attention was drawn to the fact that Manchester Civic Week was to be observed between the 3rd and 9th October. The Lord Mayor of Manchester, it was reported, had communicated with the President, and had suggested that the Institute might organise a Textile Exhibition during that week. The Council, however, appreciated the difficulty of organising an exhibition which would be of interest to the general public, and which would indicate the scope of the Institute's activities. The suggestion was forthcoming that in the event of any wireless broadcasting programme being arranged in connection with the Civic Week, the Institute would be pleased to undertake contributions thereto.

Work of the Propaganda Committee

This Committee of the Institute, formed some time ago to deal with special matters in relation to propaganda, has made substantial contribution to the activities of the organisation. At the outset the prospects appeared to be that its work would be of a more or less temporary character. Latterly, however, the demands upon it have increased and it would appear that its permanence will prove necessary. Already, the newly-constituted Council has referred many matters of organisation to this Committee, including special consideration of more or less difficult problems in connection with the advancement of certain of the Institute Sections. So far as sectional activity in Scotland is concerned, special difficulty arises owing to the somewhat long distances which separate the respective textile centres. The Propaganda Committee will also give consideration to a movement for resuscitating the Section Committee at Belfast, in which connection it is gratifying to record that Mr. F. Anderson, of Portadown, has kindly consented to assist in this direction. The Propaganda Committee is also charged with giving consideration to the interest which the Institute might develop in connection with the meeting of the British Association at Leeds in 1927.

Membership of the Institute

At the June meeting of the Council, the following were elected to membership of the Institute—Messrs. Norman H. Buckley, 1 Hardwick Street, Keighley, Yorks. (Pupil to Patent Agent); F. Arthur Burden, 229 Regent Street, London W.1. (Export Manager, Hosiery Firm); Joseph Clay, The Riddings, Long Preston, Leeds (Wool and Yarn Merchant); John H. Cooke, 17 Altrincham Street, Manchester (Velvet Manufacturer); James Duckworth, 139 Cleaver Street, Burnley, Lancs. (Assistant, Weaving Department, British Celanese Ltd., Spondon, nr. Derby); Edward Dunkerley, 32 Brewerton Road, Oldham (Cotton Mill Carder and Teacher of Cotton Spinning); W. C. Fenton, Spen Hall, Cleckheaton, Yorks. (Mechanical Textile Manufacturer); Leon. Frenkel, 153 Moorgate, London E.C.2 (Olive Oil Producer); Norman Gregson, 219 Greenmount Lane, Heaton, Bolton (Cardroom Apprentice); Thomas Hadfield, 19 Kelvin Street, Darwen (Textile Chemist); Miss Regine Hausman, c/o *Manchester Guardian Commercial*, 3 Cross Street, Manchester (Journalist); Messrs. Frank Hill, "New Lynn," Livesey Branch Road, Livesey, Blackburn (Teacher of Cotton Spinning); James T. Hodgson, Bastwell Dye Works, Blackburn (Chemist and Dyer); Dr. H. B. Holsboer, Director of The High Textile School, Enschede, Holland; N. D. Long, 20 Park Row, Leeds (Textile Specialities); Beaumont Mettrick, 112 Woodside

Road, Huddersfield (Teacher of Textile Technology); Charles E. Mullin, 3rd and Jackson Streets, Camden, N.J., U.S.A. (Consulting Chemist); Percy Rhodes, 40 Reevy Road, Wibsey, Bradford, Yorks. (Weaving Manager); Harold M. Scott, c/o Messrs. Robert Clay Ltd., Cheadle, Cheshire (Textile Chemist); Allan Tempest, Cawnpore Woollen Mills, Cawnpore, India (Manager, Worsted Carding and Combing); Thomas C. Woodman, 9 Hampton Road, Teddington, Middlesex (Textile Scientist).

COMMUNICATIONS

To the Editor

Dear Sir,—On page P62 of the *Journal* for April 1926 in the report of the discussion which followed the paper by Mr. G. H. Buckley on the knitting of artificial silk, the following statement is attributed to the lecturer—"—in the making of lace, which is, of course, a twist and not a loop fabric."

Mr. Buckley must have overlooked the fact that one of the earliest forms of needle-point, that is, crochet lace, is entirely a loop fabric, and further that the button-hole stitch used in making the "vrai reseau" of needle-point lace is itself a loop.

In addition, I would point out that for many years loop laces have been made on the Levers lace machine, the warp lace machine, and all the modern derivatives of the latter, including the Hakel-galon or crochet lace machine. It is evident that there is some confusion concerning the stitches which are the basis of lace, and this confusion appears to arise from the fact that all knots, crochet loops, and button-hole stitches are twist—and therefore lace—loops clearly distinguishable from the plain or weft loop known as the knitting stitch.

It is the custom in the hosiery trade to-day to talk of warp knitting and weft knitting. Since the stitch is a mechanical unit upon which all textile construction is based, it is necessary to distinguish plain, that is non-twist stitches, from twist or lace stitches, and I venture to assert that the modern classification of knitting, so far as it classifies openwork twist-loop fabrics as hosiery, instead of lace, is in error.

Yours faithfully,
(Signed) JAS. L. LITCHFIELD.

To the Editor

A Case of Woodboring Beetles Damaging Bobbins and Yarn

Dear Sir,—There has recently come under my observation a case of a textile fault which is unique in my experience and knowledge. Worsted yarn had been wound into cheese form on wooden bobbins which had become infested with woodboring beetles of the species *Anobium punctatatum* De Geer, the common furniture beetle. The larvæ of this beetle are small, six-legged, whitish grubs which live inside wood, drawing their nourishment from the wood itself and always remaining hidden below the surface so that a piece of wood may be honeycombed and rotten with their tunnels or burrows, and yet apparently sound. On reaching maturity they burrow to just beneath the surface of the wood and there make a cell in which they pupate. When the beetle emerges from the pupa it waits until its body and jaws harden and then bores its way to the outside where it immediately goes in search of a mate. The larvæ are specially adapted for living in burrows inside wood except when newly hatched or very young. They have the greatest difficulty in walking or even moving about at all on the surface, and in any case could not derive their necessary sustenance from wool. A very good account of the life and habits of this and other woodboring beetles commonly found in this country together with the methods of dealing with them is given in "Furniture Beetles," by C. J. Graham, D.Sc., being Economic Pamphlet No. 11 issued by the British Museum (Natural History).

In the above case the presence of the beetles was not discovered until the yarn came to be unwound, when it was found to be cut up into short lengths and so totally ruined. The mature beetles had made their way out of the bobbins and tunnelled through the yarn also. The bobbins were absolutely honeycombed with the powder-filled burrows of the larvæ and numerous holes about $\frac{1}{16}$ inch in diameter were to be seen where the mature beetles had made their way out.

The yarn also was cut up and totally ruined by the long straight tunnels drilled through it by the beetles in escaping. It is perhaps as well to emphasise the fact that it was the mature beetles and not the larvæ which damaged the wool and that the wool afforded them no nourishment at all and was attacked because it happened to be in the way to freedom. In normal circumstances there is not the slightest danger of the beetle attacking wool or any other textile fibre. So far it has not been possible to ascertain where or when the bobbins became infested with these beetles. That it happened before they left the spinners is certain, as unfortunately the trouble was not discovered until the greater part of the yarn had been delivered to various customers; in fact, attention was first drawn to it by complaints arriving in from several of them. The fact that the trouble came to a head in several widely separated places proves that it was not a case of infestation after leaving the spinners' hands. The beetles may have been present in the wood the bobbins were made from or the bobbins may have become infested later whilst in store. Apparently there were no signs of their presence when the yarn was wound on to the bobbins, but it is well to remember that even if there had been a few worm holes visible at that time, it is hardly likely that the operative would have noticed them, or even if she did that she would have known what they were. Although of course the destruction of the yarn and the annoyance caused the customers is serious it is by no means the worst feature of the case. The real trouble is that for the next few years it will be necessary to be on the lookout for, and take precautions against, this wood pest in all the sheds in which these bobbins have been, because there is every possibility that the beetles which have emerged have mated and may have subsequently infested the woodwork present in the sheds both as structural parts such as beams and floors, and also in the form of bobbins, skeps, and machine parts.

Yours faithfully,

(Signed) C. O. CLARK.

REVIEWS

Rubber and its Uses in Building Works. H. P. Stevens and B. D. Porritt. Issued by the Rubber Growers' Association, Inc., 2, 3, and 4 Idol Lane, London, E.C.3.

A brochure issued by the Propaganda Department of the Rubber Growers' Association with a view to stimulating more general use of rubber in trades and industries. Written by two experts in the rubber industry, the text is in no sense a catalogue of articles and products of which rubber forms the basis, but a broad outline of the substance and the modifications of which it is capable to meet special requirements. The qualities of rubber render it particularly suitable to solve many of the technical problems of the great industries, and the policy of the Association is, therefore, to bring directly to the notice of those engaged in those industries the possibilities of rubber to produce more efficient working, to reduce costs, and to obtain better service. The Secretary writes that the Association will be pleased to supply copies of the booklet on application to him.

J.D.A.

Die Kunstseide. By Dr. Valentin Hottenroth. (Verlag von S. Herzel, Leipzig, 1926.)

In the introduction interesting facts concerning the growth and properties of natural silk are given; then follows the historical development of the artificial silk industry. Réaumur in 1734, in his *Memoire pour servir a l'histoire des insectes*, Vol. 1, p. 154, explained that it must be possible to make fine fibres like silk from solutions of gum or gum-like substances. Braconnot in 1832 made explosive Xyloidin which Schonbeim in 1846 applied as gun cotton, and Audemars in 1855 (E.P.283, 1855) made artificial fibres from solutions of gun cotton in ether and alcohol with addition of rubber. It may be mentioned that some 3,000 years

ago the secretion of silk worms was applied in a similar way for making fibres in the East. E. J. Hughes (E.P.67, 1857) described the preparation of artificial fibres from starch, glue, gums, tannins, fats, &c. Ozanam (*Comp. Rend.*, 1862, Vol. 55, p. 833) proposed to make fibres from a solution of real silk in Schonbeim's solution. In those days chemistry and technology were not ripe for the development of artificial silk. Swan, in 1880, applied cotton fibres, parchmentised with sulphuric acid for the manufacture of carbon filaments for electric light bulbs. Crookes in 1881 used a solution of cellulose in ammoniacal copper oxide, Robertson a solution in zinc chloride, Weston, in 1883, a solution of cellulose nitrate, while Swan, in 1884, used a solution of cellulose nitrate in acetic acid. The *J. Soc. Chem. Ind.*, 1885, **4**, 34, refers to Swan's artificial silk as a new spinning material. Chardonnet in 1884 applied a method very similar to that of Swan, and floated a company for 6,000,000 francs to exploit the process in Besançon; the company lost considerable sums of money and did not pay a dividend until 1894. Another company floated in Speitenbach, Switzerland, also met with difficulties. Other works were erected in Glattbrugg (Switzerland) by Lehner; at Bobingen (Augsburg); Kelsterbach-a-Main; Sarvar (Hungary); Padua and Pavia (Italy); Wolston (England); and also in Belgium (Tubize Company, 1906); In consequence of the explosive nature of cellulose nitrate, attention was paid to other solutions of cellulose and the use of Schweitzer's solution, discovered in 1857, and applied by Weston in 1882, was adopted, notably by Despaissis in France in 1890, and later by Fremery and Urban in Germany. The Vereinigte Glanstoff-fabriken A.-G. was formed at Aachen in 1899 and transferred to Elberfeld in 1909, the works being at Oberbruch (Aachen) and Niedermorschweiter, Mulhouse. Companies related to this were La Soie Artificielle, Paris; and Niederosterreichische Glanzstoff-fabrik A.-G., Vienna, which in 1906 were producing at St. Polten 125 kg. per day, and also the British Glanzstoff Manufacturing Co. Ltd., at Flint (eventually taken over by Courtaulds' Ltd.). In 1891 Viscose was discovered by Cross, Bevan, and Beadle, the patent rights being acquired by Furst Guido Donnersmarck Kunstseide and Acetatwerke, formed to produce 500-600 kg. per day, in Germany, and by Courtaulds in England. The acid salt coagulating bath of Muller and Koppe, patented in 1905 and modified in 1910, obviated most of the difficulties of viscose spinning. Both these patents have now expired in England. Cellulose acetate was first produced in 1865, but not in considerable quantities until recently. Even in 1925 it was not quite decided whether this silk would play a very important part in industry. The difficulties of producing a marketable, especially a level-dyeing product, are very great and have delayed large scale development. Only in recent times have there been any large schemes projected such as those of the British Celanese Ltd., American Cellulose & Chemical Co., and the Lustron Company in America.

One can divide the manufacture of artificial silk into three sections—the preparation of the spinning solution, the spinning process, and the finishing operations. Raw materials are of great importance in the manufacture of spinning solutions, and in the spinning process both the apparatus and the spinning bath must be considered. The finishing processes include washing, bleaching, drying, twisting, dyeing, finishing, &c. All artificial silks of technical importance to-day are cellulose products, and the properties of cellulose are described. An account of the growth of various kinds of cotton fibre is given with much information concerning the properties of cotton cellulose. Mention is made of the recent work of Herzog on the crystalline character of cellulose and a short account of the recovery of linters from cotton seeds is given. An account of the origin, manufacture, and properties of wood pulp follows, with tables showing the percentage of cellulose in different kinds of wood and the amount of pentosan derivatives obtained from each. The manufacture and bleaching of soda-cellulose, sulphate-cellulose, and sulphite-cellulose is described. The impurities in wood-pulp are considered. Other forms of cellulose as well as non-cellulosic compounds used in the manufacture of artificial silk are dealt with. The mechanical and chemical processes applied to cotton to render it suitable for use in the manufacture of artificial silk are described. The important points in the spinning solution are the concentration of the cellulose, the viscosity of the solution, its precipitability, and, finally, its purity. It must be free from particles which might fill up the fine openings of the spinning jets. The spinning process varies with the cellulose compound used as also does the

spinning bath. The following important points are dealt with—the spinning jets; the methods of twisting simultaneously with spinning; the spinning pumps, both wheel and piston; the final filtration process and apparatus; special forms of spinning jets including the rotating jet; the bobbin system of spinning and the centrifuge method. Prints are given of the machinery of O. Kohorn, and C. G. Haubold, of Chemnitz, but not of other firms either in Germany or elsewhere. Several methods of washing and drying bobbins are shown, also methods of twisting and reeling the dried silk. The drying of hanks under tension after centrifuge spinning is mentioned, and bleaching and finishing as well as sorting and testing artificial silk are dealt with in general. The book also deals with special individual methods of manufacturing artificial silk, 72 pages being devoted to nitrocellulose silk; 38 pages to cuprammonium silk; 50 pages to viscose silk; 22 pages to acetate silk; 8 pages to cellulose-ether silks; and 11 pages to various other kinds of silk not of technical value. In relation to nitrocellulose silk the preparation of the cellulose from cotton is first considered, then the theoretical points concerning cellulose nitrates, and after this the practical carrying out of the process of nitration and subsequent washing purification and dyeing, and the recovery of acids. The properties of the cellulose nitrates are considered. The preparation of collodion solutions in the various known solvents is discussed and the wet and dry spinning of collodion silk described, also the de-nitration, washing and drying of the silk as well as the methods of recovering the solvents. In the cuprammonium process the chemistry of the copper compounds with alkalies is dealt with. The preparation of the raw materials, cellulose, and ammoniacal copper solution are described, following which the dissolving of the cellulose in the copper solution and its subsequent filtration are set out. The two methods of spinning using respectively acid and alkaline coagulating baths are considered as well as the stretch spinning process. The removal of copper, recovery of chemicals, and the washing and drying of cuprammonium silk are mentioned. The viscose process is also described in detail, viz., preparation and ripening of alkali cellulose; sulphiding and ripening of viscose solutions; spinning and after-treatment of spun fibres to the finished state. The methods of analysis of viscose, several of which were originated by the author, are given in detail. The various spinning baths proposed for viscose silk spinning are mentioned, including the recent inventions. The acetate and ether silks are not described so fully, presumably because the literature on these subjects is rather diffuse and information of practical value is not yet public property. The dyeing of artificial silks is dealt with in 16 pages and includes short accounts of all the processes applied to acetate silk. The physical and chemical properties of artificial silk are given in 14 pages. The application of artificial silk in weaving, alone, and with other fibres is dealt with as well as several other special subjects. Figures of production in various countries since 1896 are given with a list of firms making or proposing to make artificial silk in 1924 as well as prices of 1st, 2nd, and 3rd grade artificial silks in America in 1925. Finally, an excellent collection of the literature on artificial silk is given. The book is entirely different in construction from that of Suvern, which is mainly a collection of patent literature, but that under notice must be regarded as the most valuable book available at the present time. W.H.

The Chemists' Year Book, 1926. Edited by F. W. Atack (Manchester: Sherratt & Hughes, 21s. net).

The eleventh edition of this very useful reference book contains, in addition to the usual articles of various phases of industrial chemistry, a new section on lubricants, the matter for which has been supplied by Mr. H. Moore. This section might advantageously have been given a little more space, as it is incomplete in many respects, notably for instance, in that no mention whatsoever is made therein of graphite. The general arrangement follows the style of past editions, but all sections have been revised, and some enlarged. In this connection it might be remarked that the section on cellulose, very ably compiled by Mr. C. F. Cross, should be extended to cover the technically important modifications of cellulose, the artificial silks, to which very few lines indeed are devoted in the present edition. On the whole, the Year Book has maintained the standard of improvement set by the early editions, and is a reference work without which few chemists would care to be. —J.E.F.

THE JOURNAL OF THE TEXTILE INSTITUTE

Vol. XVII JULY 1926 No. 7

PROCEEDINGS

NOTES AND NOTICES

Council of the Institute

Although there was a lengthy programme of matters to be dealt with at the meeting of the Council of the Institute on Wednesday, 21st July, nevertheless the business was transacted with commendable dispatch. Unfortunately, the President (Mr. W. Howarth, J.P.) owing to a business engagement in London was unable to attend, whilst Mr. John Crompton (Chairman) was also unable to be present. Mr. W. Frost (Macclesfield) was voted to the Chair, and others present were Messrs. T. Fletcher Robinson, F. Nasmith, J. C. Withers, H. P. Greg, W. W. L. Lishman, W. Kershaw, A. B. Shearer, E. A. Swift, H. Binns, S. Watson, C. S. Ickringill, H. Nisbet; and the General Secretary. The correspondence, dealt with at the outset, included a letter from the Federation of British Industries asking the Council to furnish information as to technical education in reference to the textile industry, a questionnaire being submitted in connection with the demand. It was decided to refer the matter to the Selection Committee. A letter from Mr. W. Harrison suggesting expansion as to both activities and premises of the Institute was referred to the Propaganda Committee. Mr. J. H. Lester wrote suggesting that the Council might usefully consider the question of re-forming the General Purposes Committee, abandoned some time ago, and it was agreed that this question be placed on the agenda for the next meeting. The appointment of standing committees of the Institute was dealt with in accordance with recommendations of a special meeting of chairmen of committees, and the proposals of certain of the committees concerned. The names of the committees, it may be expected, will be published in the next issue of this *Journal*. There were seven elections to membership and, in this connection, the Council approved of a new form of application for membership of the Institute, the form providing for considerable additional information to be supplied by applicants. The Hon. Treasurer (Mr. T. Fletcher Robinson) submitted the financial statement which indicated that the balance at bank on current account would be small after payment of accounts to date. The Finance Committee had met that morning and recommended a policy of conservation with regard to income from Diploma fees and Life Membership subscriptions. The Council readily approved of the recommendation that the balance in favour of the diplomas account at the end of the present financial year be invested in War Stock, and that a similar course be pursued with reference to all new subscriptions for Life Membership on and after 1st January next. It was agreed that the General Secretary should visit Belfast in September in order to carry out the suggestions of Professor Bradbury and Mr. F. Anderson (Portadown) regarding reorganisation of the Section for the Belfast district. The Annual Conference of the Institute

which was postponed from Whit-week last is to be held, if possible, about the third week in October, and the General Secretary was asked to take steps to ascertain how far the original programme could now be carried out. It was decided that next meeting take place at the usual time—2.45 p.m.—at the Institute's head-quarters on Wednesday, the 22nd September, no meeting to take place during the month of August.

Applications for Appointments

Employer-members of this Institute are making increasing use of the services of the Institute in regard to the securing of suitable candidates for vacancies in employment. Conversely, members in pursuit of occupation frequently register particulars of their claims for consideration in connection with vacancies. Many cases might be recorded wherein the services of the Institute have proved of mutual advantage to both employer and employee. The complaint has been made that the textile industry does not readily absorb all those young men who have submitted to a prolonged period of special training and secured commensurate qualifications, but it might be useful to suggest that more attention on the part of the applicant for engagement should be given to the manner in which he approaches the industry. The experience of the secretarial department of the Institute in reference to applications for vacancies received at the Institute for forwarding to the employer, has, in several instances proved disappointing. Applicants have submitted applications prepared in a perfunctory manner, with the records of experience set out without the slightest regard for order of presentation. In one instance, recently, an application was returned with the suggestion that better paper should be used and that either the handwriting should be more legible or typewriting resorted to. If applicants are not at least reasonably painstaking in the preparation of their applications, then they must not complain if their efforts prove futile.

Section Committee Meetings

Arrangements are proceeding with reference to the promotion of Section meetings for the delivery of papers, followed by discussions, during the coming Autumn and Winter months. The Yorkshire Section has already announced its intention of holding meetings at Bradford, Keighley, Batley, Huddersfield, and Halifax, and it is intended to secure as far as possible the co-operation of local textile societies in the promotion of the meetings. The President of the Institute (Mr. W. Howarth, J.P.) has kindly promised to address a meeting at Bradford, and this event will take place jointly with the Bradford Textile Society, whilst members of the Shipley Textile Society are to be invited to attend. The Lancashire Section Committee of the Institute has already held one useful preliminary meeting in reference to its programme for next session. It is proposed to hold a series of luncheon meetings at which short addresses will be given dealing with various aspects of the textile industries of foreign countries. It is also proposed to hold meetings in Macclesfield, Preston, and Leicester during the session. In the early part of next year, Sir W. H. Himbury, of the British Cotton Growing Association, will contribute a paper at Manchester on the subject of Empire cotton supplies. It is also proposed to endeavour to reconstruct the Northern Ireland Section of the Institute, whilst in Scotland one or two meetings are contemplated, an arrangement having already been reached for a paper to be given at Dunfermline in the latter part of the year.

Fellowships and Associateships

Up to the present time, the announcements of the grant of Institute Diplomas to its members represent the issue of 80 certificates of admission to Fellowship and 52 of admission to Associateship. So far, the Selection Committee of the Institute has had a difficult and exacting task to perform. From the outset,

it was recognised that in the early stages it was not advisable to set up definite or binding regulations. The Committee preferred to be guided by experience in dealing with early applications. It is interesting to note, however, that the stage has now been reached at which the Committee is taking steps in the direction of the formulation of regulations to be rigidly adhered to in the case of future applications. In due course, doubtless, some announcement will be issued by the Committee, and a date subsequent to which new regulations will be rigidly adhered to may be fixed. Already, one examination of candidates has taken place (candidates for Associateship) and a similar examination is to be held in September. In due course, however, it is hoped to frame a syllabus indicating the requirements of the Committee, and a meeting will be held at a comparatively early date for the special purpose of giving full consideration to the provisions of the proposed syllabus.

Design and Structure of Woven Fabrics

Under the Lieutenant Crompton Memorial Scheme, this Institute is enabled to offer annual awards of over £100 in prizes with a view to the improvement of design, colour, and structure of woven fabrics. It is felt that a scheme of this kind might be of far greater service to the industry if more definite and direct interest on the part of manufacturing and other interests were secured. Suggestions with a view to modification and improvement of the existing scheme of competition have recently been submitted to the Committee of the Institute in charge of the scheme. In order that details of the scheme may be fully considered, it has been decided to hold a conference of the Committee and of representatives of various textile organisations and technical colleges and schools at the Institute, at Manchester, on the afternoon of Saturday, 11th September. The funds available for the scheme are quite adequate for the purpose, and additional co-operation is desired solely in order that the utmost advantage may be secured by the operation of the scheme. It is confidently hoped that as a result of the Conference the details of the annual competitions may be considerably improved. It may be mentioned that since the scheme was put into operation a few years ago, several revisions of the prospectus have been carried out. Whilst the quality of the productions of the competitors has definitely improved, yet the number of competitors secured each year is usually not so large as should be the case in a competition offering such substantial rewards to the successful participants.

Diplomas of The Textile Institute
Awards of Fellowships and Associateships

FELLOWS

BERRY, Frank (Bolton).
BROADBENT, James Thomas (New York).
BROMILY, Harold (Cloughfold, near Manchester).
VERNON, William (Cawnpore, India).
WILKINSON, William (Blackburn).

ASSOCIATES

ADAN, John McKay (Aberdeen).
BOSWELL, William Ernest (Nottingham).
CHRISTIE, David Robert (Galashiels).
DEY, J. Nath (India).
GOULDING, John (Woolfold, Bury).
HARTLEY, Hiram (Potternewton, near Leeds).

Elected to Institute Membership

At the July issue of the Council, the following were elected to membership of the Institute—A. R. Baines (Woollen Manufacturer), Southfold, Morley, near

Leeds; S. E. Illingworth (Worsted Textile Manufacturer), Messrs. Thos. Priestley and Sons Ltd., Bank Top Mills, Great Horton, near Bradford; W. Lees (Spinner, Teacher of Textile Technology), 58 Osborne Street, Oldham; Herbert Nutter (Retired Manufacturer), Ash Lea, Bagslate, near Rochdale; R. S. Spreckley (Textile Designer), 34 Cowper Place, Bradford; John P. Twohig (Textile Designer and Technical Teacher), 163 Victoria Terrace, Undercliffe, Bradford; G. Waddington (Textile Student), Springfield, Haslingden, Rossendale.

Linen Industry Research Association

Dr. W. H. Gibson, O.B.E., F.I.C., F.Inst.P., has been appointed Director of Research for this Association in succession to Dr. J. Vargas Eyre. Dr. Gibson was educated at University College, London, under Professor Sir William Ramsay, and is Doctor of Science in Chemistry of London University. He spent twelve years at the Research Department, Royal Arsenal, Woolwich, and for his services in connection with high explosives research during the Great War was awarded the M.B.E. in 1918 and the O.B.E. in 1920. For the last seven years Dr. Gibson has held a responsible position in the linen industry, having been in charge of the research department of one of the most prominent linen firms in Belfast. Dr. Gibson is a member of the Textile Institute, and has frequently contributed to the Transactions Section of this journal.

COMMUNICATIONS

The following correspondence is published by the consent of the originator, Mr. G. J. Fleming, manager of the Kassala Cotton Co., Aroma, who agreed to this course in the hope that members of the Institute would contribute any information or suggestions they may have upon the matter. Other letters have been specifically sought and in most cases definitely promised, and it is intended to publish these with any that may be forthcoming as a result of publication, in later issues.—EDITOR.

To the Editor

Dear Sir,—I have for many years held the opinion that a very great development could take place in wool production in this country. I have advocated the advisability of introducing the merino sheep to cross with the existing native sheep but no progress has yet been made. I still live in hope, however. There is a certain amount of information which I require and with which I feel sure you could furnish me or at least could put me in the way of making further investigation. The position is this—A belt runs across the whole breadth of the Sudan and in this belt live a great number of sheep. The rainfall of this belt varies from 10-30 inches per annum and is confined to four months in the year. North of this line, there is not enough grazing; south of this line, the soil is too heavy and the sheep do not thrive. The following table gives the mean average yearly temperature taken over a period of 16-18 years in three towns in the sheep belt.

Temperature		Evaporation	Relative humidity
Maximum ° C.	Minimum ° C.	("Piche" scale)	(per cent.)
36·8	21·1	10·22	44
34·7	17·7	13·58	39
37·4	20·0	13·15	38

The average maximum monthly temperature rises to 41·9° C., while the average minimum can fall as low as 11° C.

The following peculiarities of the Sudan sheep should be noted—

(1) They have a very thin fleece and most of the fleece is composed of hair The fleece at present is not worth removing as a commercial product It is woven into very coarse coverings by some tribes.

(2) All the Sudan sheep have long legs, as they require to walk a great distance to water.

I wish to know if, under the circumstances, it is practical in the opinion of experts to import a wool type of sheep, who could stand these conditions of environment and climate. Owing to the heat and the great distances they require to graze over in order to gain their existence, it is impossible to expect sheep in this country to carry large fleeces. I am sanguine enough to hope, however, that it may be possible to breed a sheep—the fleece of which will at least be worth shearing and exporting. If the proper sheep can be bred, it means that the improvement of sheep husbandry from the Red Sea to Lake Chad is in sight and will affect several thousands of flocks.

(Signed) G. J. FLEMING *Manager*
Kassala Cotton Co. Ltd.

Aroma, Sudan, *6th April* 1926.

To the Editor

Dear Sir,—My reply to Mr. Fleming's letter is as follows—

(1) The average rainfall per annum is probably not an important figure, but 10″—30″ per annum, properly distributed, might be reasonably satisfactory.

(2) The distribution of the rainfall is the important matter, as even the Australians recognise. It seems to me, therefore, that the whole of the rainfall being confined to four months in the year makes the proposition of introducing further types of developed sheep problematical.

(3) The temperature difficulty can almost certainly be met by providing the correct type of animal.

(4) It would seem very desirable to maintain certain characteristics of the Sudan sheep, particularly

(*a*) The long legs to enable it to travel; and

(*b*) A large body, by the cubicle contents of which moisture, &c., may be better retained than by a small body.

What is the critical volume for a sheep in this part of the country can only probably be worked out by breeding experiments.

(5) The food conditions would suggest a desert acclimatised Australian or South African merino, but great care would have to be exercised in selecting for type, otherwise the unfortunate experience of Australia with the Vermont merino during the great drought might be repeated.

If Colonel Stordy were to recommend the trial of the Peruvian merino, it might be possible to get examples from the stud flock in this country at Reading College.

(Signed) ALDRED F. BARKER
Professor of Textiles.

Department of Textile Industries,
The University, Leeds,
26th April 1926.

To the Editor

Dear Sir,—Many thanks for your letter enclosing a copy of Mr. Fleming's original letter. I am afraid that we in this Department have no special knowledge of the problem involved and can only give you some general impressions

First, with regard to climate, there would seem to be no reason why strains of Merinos should not be found that would be suitable for the hot, dry climate. South Australia and Arizona occur to one in this connection. The Merinos that are bred in the former area are large and well calculated to resist drought. Professor L. J. Cole, of the University of Wisconsin, should be able to provide valuable information upon analogous conditions in America. If a small flock of suitable Merinos were imported into the Sudan, they could be observed as a pure flock, and the result of hybridisation with the native sheep could be investigated. It

would be necessary to secure as much information as possible before selecting the type considered likely to be suitable, but the matter could only be settled by direct experiment.

Secondly, I am doubtful about the importance of long legs. This may be necessary, but need not, I think, be taken for granted until the point is tested.

Thirdly, a point that may be a deciding factor is the question of parasites, both external and internal. This can only be settled by experiment. It would be seen whether a pure Merino flock flourished or was badly affected. If they were found to be very susceptible, an attempt would have to be made to preserve in the grading-up process the natural relative immunity of the native stocks.

I should imagine that the Peruvian sheep would be a doubtful proposition owing to the fact that their habitat is at a very great elevation above sea-level and the rainfall is not low. The first step should be to obtain first hand information of the breeding of Merinos in those areas where the physical conditions most closely resemble those obtaining in the Sudan.

Animal Breeding Research Department,
University of Edinburgh,
King's Buildings, Edinburgh,
24th May 1926.

To G. J. Fleming Esq., Kassala Cotton Co. Ltd., Aroma, Sudan.

Dear Sir,—Mr. Hugh L. Robinson, Editor of the *Journal of the Textile Institute*, has forwarded to me your inquiry in regard to the advisability of introducing improved breeds of sheep into the Sudan. I fear my personal knowledge of the conditions, as well as of the breeds of sheep, is so limited that I cannot give you specific advice. I am accordingly taking the liberty of forwarding your letter and Mr. Robinson's request to our Federal Department of Agriculture. I think our experts in sheep husbandry in the Animal Husbandry Division of the Bureau of Animal Industry can, perhaps, from their wide experience with breeds and conditions in this country, give you suggestions that may be of value.

As to the methods of breeding to be employed after improved sheep have been introduced, several different ones are possible and what would be best to employ will depend largely upon local conditions.

First, if an established breed can be found having the desired qualities and able to meet the climatic conditions, the simplest method is, of course, simply to continue to breed it as a pure breed which should gradually supplant and replace the native unimproved sheep. I doubt whether pure bred Merinos would thrive under the conditions, but if they were to be tried I would suggest the Rambouillet as perhaps being better suited than the other types.

Second, another method would be to introduce a suitable improved type and use the males for breeding on native ewes, thus gradually grading the stock up toward the improved breed. This method, like the first, would be suitable only in case the improved breed were one adapted to the conditions of the country.

Third, it is quite possible that the crossbred sheep obtained from breeding the improved rams on native ewes would be superior in quality to the native sheep and at the same time would be hardier and better adapted to conditions than the pure bred improved type. This might indicate the desirability of a continued system of cross-breeding, the details of which would have to be worked out according to circumstances. In some of our western states, for example, it is a common practice to alternate the use of Rambouillet and Hampshire rams on what are called the native "western ewes." By this means a balance is maintained in quality of wool, mutton type, and herding instincts which gives a sheep better than either of the pure breds used. It is quite possible that some

such system as this would work out to best advantage in your country, but just what crosses would give the best results would probably have to be determined to considerable extent from trial.

I trust that you may receive some suggestions of value from Washington.

REVIEWS

Les Tissues Impermeables. By D. de Prat. Second edition. Published by Libraire Polytechnique Ch. Béranger, Paris.

The book is divided into two sections—the first dealing with waterproof fabrics and the second with fabrics impermeable to gases such as are required for balloons, &c. A description is given of the methods of rubbering fabrics; of the waterproofing of fabrics with aluminium acetate; with aluminium soaps, more particularly aluminium oleate; with copper salts, particularly Schweitzer's reagent as used in the Willesden process, and, finally, with other metallic compounds such as the oxides of antimony, tin, lead, and zinc. The methods of waterproofing with paraffin wax applied in liquid form and in solution are described, following which processes using gelatin, glue, tannin, gelatin bichromate, calcium caseinate, albumen, solutions of cellulose, &c., are dealt with. Chapter IV. deals with various methods requiring the use of metallic salts, soaps, silicates, gelatine, gums, drying oils, rubber, and cellulose compounds. An account is given of the application of electricity in the waterproofing of fabrics with aluminium oleate. The aluminium oleate formed in the fibre by impregnation with a soap solution, followed by a solution of aluminium sulphate, is subjected to electrolysis whereby the aluminium oleate is said to be converted into a basic oleate insoluble in benzine and other solvents used in dry cleaning. Various methods are given for the determination of the resistance of waterproofed fabrics to air, light and air, washing, use, and perspiration. Appendices are given dealing with tarpaulins, and such fabrics as taffetas, moleskins, &c. In considering fabrics impermeable to air, the treatment of aeroplane fabrics with agar-agar and formaldehyde, followed by collodion, is described, also the use of cellulose acetate. Methods of preparing balloon envelopes from cotton, silk, and linen by treatment with varnishes containing linseed oil, guttapercha, rubber, &c., are given, but the main part deals with rubbered fabrics. Methods for determining the impermeability to air, hydrogen, &c., are described. W.H.

Chemistry and Practice of Finishing. By Percy Bean and W. McCleary. Published by Hutton, Hartley & Co. Ltd., Manchester. (2 vols., pp. 624 and 396. Price, 60s.)

The third edition of this well-known work has been carefully revised and considerable new matter incorporated, thus bringing it up to date and rendering it not only suitable for students and apprentices, but useful as a work of reference to the practical finisher. Its value is not confined to those intimately bound up with the finishing trade but it will appeal to a wide circle embracing many who are only indirectly interested since finishing is only one link in the textile chain.

The first volume deals lucidly with the practical bleaching of cotton and linen fabrics and the materials used in the finishing of either. It also deals with the method of analysis of such materials in a manner readily understandable by those whose knowledge of chemistry is somewhat limited. Photo-micrographs by Mr. A. Flatters, and an account of the main textile fibres form an interesting introduction to the chapters dealing with the various chemicals used in bleaching. The question of the quality of the water used in textile processes is also adequately dealt with. The whole may be profitably digested by the practical bleacher. The chapters dealing with the important problems arising out of the bleaching of cotton goods containing artificial silk and of cotton fabrics containing coloured yarn are well written. There are certainly difficulties to be overcome in treating

goods under both the above headings. It is necessary to emphasise that many of the troubles which arise in bleaching these fabrics are due to ignorance and carelessness preparatory to the goods being bleached. Comment might have been made on the difficulties experienced by the bleacher from the indiscriminate use of mixed brands of artificial silk which is comparable to the trouble repeatedly found in cotton fabrics made from indifferent mixings. The chapter dealing with machinery is comprehensive and well illustrated; the essential principles being adequately defined. The three closing chapters of the first volume deal very fully with the questions of stains and faults in cotton fabrics and will merit thorough digestion by all employed in the textile industry. Part 2 is devoted to an account of the substances used in finishing and conveys some idea of the complexity of the intricate processes necessary to enhance the value of an ordinary piece of woven cotton fabric.

The second volume gives a fairly complete account of the finishing of cotton goods. The necessary machinery is described, and in addition a number of patterns are given showing various finishes. Taking into consideration that present-day finishes are numbered by the thousand, the patterns here displayed are fairly representative and must be useful to those in the industry who are responsible for this branch. Apart from a few paragraphs—e.g., page 132 on "Carbonyl Chloride," and page 151 on "The Use of Liquid Chlorine" ("writ sarcastic") no serious criticism is offered and the work will meet with appreciation by all interested directly or indirectly in the bleaching and finishing industry.

—W.K.

La Ramie. Culture et Succédanés. By Felicien Michotte. (Soc. de propagande coloniale, 45 Avenue Trudaine, Paris. Tome 1[er], 158 pp. and Index. 10s. net.)
At the conclusion of the preface of the first edition of his now well-known work, published in 1890, the author stated "Ramie is the textile fibre of to-morrow." While it is highly improbable that the material will ever satisfactorily replace the staple vegetable fibres in common use, there is no doubt that extended utilisation of ramie in the textile industries merits further consideration, and one therefore welcomes publications on the subject. The present monograph represents a re-edited and amplified version of a part of the first edition. It would have been enhanced by the omission of the early portion, in which the author replies to the criticisms of his earlier work. A brief account of the external and internal morphology of China grass, and a description of the animal parasites attacking the plant are given and are followed by an exhaustive treatment of its cultivation, and of processes for recovering the fibre employed in various parts of the world. The writer pays special attention to decortication methods, having devised a machine for the purpose. Dealing as it does in detail with the geographical distribution and culture of ramie and of allied members of the *Urticaceæ* family, the present volume will be of greater interest to the economic botanist and tropical agriculturist than to the textile technologist. —F.L.B.

Shirley Institute Memoirs. Vol. IV., 1925. Shirley Institute, Didsbury, Manchester.
Those in the process of forming scientific and technological libraries will welcome the appearance of the fourth volume of the Shirley Institute Memoirs, in that one obtains in collected form the non-confidential researches published by members of the staff of the British Cotton Industry Research Association in this *Journal* during the past year. Altogether, fifteen papers are presented; they deal with problems connected with the chemical constituents of the cotton hair, with spinning, sizing, mercerising, and dyeing. Details of investigations into common faults in cotton goods and the development of fungal growth in sizing materials employed in the cotton industry also appear. Papers of special value to those interested in colloids generally have been contributed by A. R. Urquhart and A. M. Williams (the brilliant physical chemist whose recent death is to be greatly deplored) and by F. D. Farrow and S. M. Neale. In every case, the researches have been carefully and exhaustively carried out, and considerable energy has been justifiably expended in the "writing up" of results. It is of course impossible in many cases to translate a scientific paper into language understandable by the average layman, but the summaries provided should enable those with no scientific knowledge to obtain a reasonably good grasp of the results obtained. —F.L.B.

Cloths and the Cloth Trade. By J. A. Hunter. Published by Sir Isaac Pitman and Sons Ltd., London. (pp. 116, price 3s. net.)

A book of interesting matter which ought to be read by all who are engaged in the merchanting of the different kinds of fabrics. Chapter 4 (Cloth-making Materials) is exceedingly good and is by far the best in the book. In the last chapter, page 82, the author, whilst dealing with the cloth warehouse might have included the various types of "make-ups" and the markets for which they are intended. On page 64, Blackburn is mentioned as making fine fancy cottons, it is noted more especially for dhooties; whilst Nelson and Colne make every type of cotton cloth (with a few exceptions) and are principally noted for coloured dress goods, as indeed the author states. Common names are given on page 66, and the author would have been well advised to explain what he meant by "plain surfaces are produced by other than plain weaves." If the author's statement that common twills "are included by most people in the category of plains" is correct, it is safe to say that "most people" have a poor understanding of cloth analysis. It is a bold statement to make (page 67) that it is impossible to decide where the one class of fabrics ends and the other begins. The next paragraph gives several names of plain woven cotton cloths, and further on the point is raised at which a drill tails off into a drillette, or a jean into a jeanette. In the trade a drill is understood as either a four or five-shaft weave, and the yarns are much heavier than in drillettes, hence we have Florentine drills, and satin drills. A drillette is a five-shaft weave and of much lighter yarns, with a preponderance of warp threads. Jeans are three-shaft twill weaves and ought to have more warp than weft, a jeanette ought to have more weft than warp, and is a much lighter cloth. But despite these criticisms, which are made in the hope of aiding a revision of the book, this addition to the "Common Commodities" series is a useful one and will be very welcome. —W.H.

The "Electrician" Annual Tables of Electricity Undertakings, 1925. Published by Benn Bros. Ltd., London. (189 pp., 10s. net, postage 9d. extra.)

An increase of 20 pages on last year's edition of these tables is due to the inclusion of particulars of many electrical undertakings which have not appeared previously. There are now statistics relating to more than 800 British and over 1,300 Colonial and Foreign concerns; all essential details being given in each case of system employed, maximum load, generating plant, price per unit, &c., together with additional information likely to be of use to engineers, manufacturers, and contractors in the electrical industry. It is difficult to understand how this book, upon which so much careful work has been obviously expended, can be sold so cheaply. —J.E.F.

Chimie et Industrie. 1914-1924*. Ten Years' Progress in Science and Industry. By various authors. Edited by Jean Gérard. Published by Soc. de Chimie Industrielle, Paris. (1,552 pp. and Index.)

The book is divided into sections dealing with ten years' progress in the various branches. General chemistry is dealt with by G. Urbain recording progress in thermo-chemistry, chemical affinity, the law of mass action and the phase rule, as well as the principle of Nernst; nothing very remarkable is recorded. Organic chemistry is written of by A. Béhal. The war is said to have hindred developments in this section and no great progress is recorded. Dealing with biochemistry, A. Desgrez mentions considerable progress in catalytic and enzyme chemistry, the constitution of proteins and hormones, and of nutrition in general. In agricultural chemistry, L. Lindet deals with progress in soil chemistry and the effect of various bacteria in soil, and refers to fatigue in soil produced by toxins.

A discussion of general conditions of scientific research in France, by Ch. Moureu, deals with the role of science during the war, science in the country, and science in industry, and mentions the organisation of scientific work in France. In a paper on analytical chemistry, A. Kling mentions new organic reagents, electrolytic and spectroscopic methods of analysis, and deals with X-ray methods of crystal analysis as well as with the application of positive rays. While M. Dienert, in an article on water, describes various methods and apparatus

* Reference was made in this *Journal* to the book reviewed above in the April 1925 issue. So far only one volume has been received; the second is in hand and notice of it will be published as soon as received—Editor.

for filtering and purifying water by physical and chemical methods, sterilisation by ultra-violet rays and chemical methods, and treatment of sewage. The three papers above referred to form part of a series dealing with scientific and technical progress in chemistry. It would be impossible in the space available to enumerate all the articles in this or the following section "L'Effort Industriel," but mention of some of the articles of more direct interest to textile technologists will serve to indicate the scope of the work. E. Audibert deals with oils; A. Baril writes on the carbonisation of oils at low temperatures; E. Damour treats with the rational utilisation of combustibles; L. Pierron discusses sulphuric acid and phosphates; A. Wahl takes for his subject colouring matters; photographic products, embracing colour sensitisation, are dealt with by A. Seyewetz; colours, lacs, varnishes, and printing materials form the subject of Ch. Coffignier's contribution; observations on latex are made in an article on rubber by R. Fric; R. Padova and E. Bontoux deal with modern work on oils and soaps; R. Auzenat writes on artificial textiles, giving a short account of progress in the well-known types; while bleaching, dyeing, printing, and finishing of textiles, including artificial silk are treated by Ch. Sunder.

In L'Effort Industriel section, interesting articles are contributed by H. de Peyerimhoff on oils; by V. Barut on electrochemistry; by J. de Kap Herr on colouring matters; by E. Roustan on soaps; by E. Carnot on artificial fibres; by H. Lagache on natural fibres and the dyeing industry; by A. Gardinier on alcohol; and by H. Hitier on agriculture.

The book is mainly an encyclopædia of modern developments and it is difficult for any reviewer to express an opinion as to its value. It is, however, a useful book of reference particularly dealing with developments in France. In most cases a good list of references is given. Individual members of the Institute would do well to refer to this book on their own subjects. A word of hearty praise for the typography and binding of the volume, which is nearly 2½ inches thick, must be added; it is as near perfection as may be in the manner in which it can be opened and laid flat at any page —W.H.

GENERAL ITEMS AND REPORTS

A Statistical Analysis of Cotton Prices for the Period 1892-1923

By Dr. Gustav Harting

(The Institute for Mathematical Statistics, Göttingen; Director, Prof. Dr. Felix Bernstein)

Translated and abridged, with the author's approval, by G. L. Schwarz, B.Sc., of the London School of Economics, from *Leipziger Monatschrift für Textil-industrie*, Sonder Nummer No. 3, September 1924; and *Leipziger Wochenschrift für Textil-industrie*, Nos. 47-49, November-December 1924.

In these articles detailed analyses are made of the statistical data for American cotton during the period 1892-1913, and 1913-1923, and from the results of the analyses, methods are suggested for forecasting future prices and movements. The various price-determining factors are examined in succession, dealing first with long period movements and working down to short-time fluctuations. A few definitions given by Dr. Harting must be first set out in order to make clear the method of investigation.

Any analysis of prices must of course deal with the figures for acreage under cultivation, yield per acre, total of harvest, and the prices themselves. In each case Dr. Harting uses the average of two years' figures to obtain what he calls the "normal," e.g.,

Average yearly price for two years	=Normal price.
Average yearly harvest for two years	=Normal harvest.
Average area under cultivation for two years	=Normal area of cultivation.
Average yield per acre for two years	=Normal yield.

The definitions will be quite clear if the tables are consulted.

The first analysis is concerned with the general tendency of prices over the 21 years, 1892–1913. The movement was downwards from 1892 to 1898, and

Table I. (No. vii. in original article)

Year	Harvest (in thousands of bales)	Normal Harvest (in thousands of bales)	Average Price in Cents	Normal Price in Cents	Difference between one harvest and the next		Difference between one average price and the next		Difference of two Harvests as % of the Normal Harvest		Difference of two Average Prices as % of the Normal Price		Deviations (12–13) (10–11)

from that time rose steadily till the end of the period. Not much statistical information is available for costs of production of cotton during the period, but a curve representing cost of production constructed from the few figures obtainable moves parallel with the curve for normal prices over the whole period except for the years 1901-1905. The movements of demand and supply are contrasted over the period. Demand is represented by the number of spindles in existence and supply by the production in bales. Parallel growth is again evident except for the years 1901-1905. The explanation of the discrepancy between cost of production and normal price and between supply and demand in 1901-1905 is, of course, the influence of the operations of the Sully corner.

The general movement in cotton prices over the period is also connected with the production of gold during those years and parallel movements are shown of cotton prices not only with gold production figures but also with the gold holdings of the banks of the Great Powers. This part of the analysis is, of course, applicable to the movement of general prices and is not confined to cotton.

The next section of the analysis deals with movements of individual years and treats cotton prices as a function of harvest results. The cotton harvest figures are compared with prices in order to find how far anti-parallelism exists between the curve for harvests and that for prices, i.e., whether prices rise or fall proportionately to the decrease or increase of the harvest.

The calculation is made by correlating the normal harvest figures with normal price figures, as is shown in Table I.

In estimating the results obtained in columns 14 and 15, any deviation less than 5% is considered to establish anti-parallelism between price and harvest. Such years are called symmetrical years. Where the percentage deviation is more than five, the anti-parallelism is not complete. Years when this occurs are called asymmetrical years (e.g., 1894, 1895, 1896, 1904, 1905, 1907, 1908, 1911, and 1912 were symmetrical years and only in half of the period under review was there complete anti-parallelism between the harvest and price curves. Explanations of the lack of correlation in the asymmetrical are given as follows—

1898—Comparatively favourable harvest and bear speculation. Failure of bull speculation based on incorrect estimates of the effect of the Spanish-American war. Prices fell below cost of production.

1899—Effects of farmers' protection policy. Beginning of Sully's corner.

1900—Sully corner taking effect.

1901—English spinners on short time as protective measure. Relieved prices temporarily.

1902—Sully corner dominated situation.

1903—Record prices.

1904—Record harvest. Systematic short time in Lancashire. Collapse of corner.

1906—Farmers' Union took active measures to prevent fall in price.

1909, 1910 } Patten and Scales attempt to corner.

The conclusion of this part of the investigation is that, apart from disturbing factors of the kind enumerated above, the tendency is for the price of cotton to rise or fall as much per cent. on the normal price as the harvest falls or rises on the normal harvest.

On the basis of this result an attempt can be made to estimate the price of cotton for the forthcoming year. Six factors are involved—

1—The harvest	for the first year	4—Normal price	for the next year.
2—Price		5—Harvest	
3—Normal harvest		6—Price	

The first four figures are available and experience has shown that a fairly accurate estimate of the forthcoming harvest can be made very early in the year. We are then in a position to calculate the price for the second year.

A simple example will illustrate the method of calculation—

In year X let	Normal Harvest	(NH_1)	$=10$
	Normal Price	(NP_1)	$=8$
	Harvest	(H_1)	$=11$
	Price	(P_1)	$=7$

Then in year $(X+1)$ if the Harvest $(H_2) = 12$, the increase as a percentage of the normal harvest is—

$$\frac{H_2 - H_1}{NH_1} = \frac{12 - 11}{10} = 10\%$$

The new price (P_2) will be such that $\frac{P_1 - P}{NP_1}$ gives the same percentage.

$$\text{i.e., } \frac{7 - P_2}{8} = \frac{1}{10} \quad \therefore \quad P_2 = 6{\cdot}2.$$

If the harvest in year $(X+1)$ is taken as 9, then

$$\frac{H_1 - H_2}{NH_1} = \frac{11 - 9}{10} = \frac{1}{5} = 20\%$$

$$\therefore \quad \frac{P_2 - P_1}{NP_1} = \frac{P_2 - 7}{8} = \frac{1}{5} \quad \therefore \quad P_2 = 8{\cdot}6.$$

The theoretical price obtained in this way can be marked on a graph of cotton prices and joined by a straight line to the point representing the price of the previous year. The line joining the two points is called the tendency line and apart from any abnormal interferences, prices during the ensuing year will be in the neighbourhood of the tendency line.

Table II. shows the results obtained by the above methods.

Table II.—Calculation of the Probable Price

Year	Harvest in 1,000 bales	Difference of harvests in 1,000 bales	Normal harvest in 1,000 bales	Difference of harvests as % of normal harvest	Seasonal Average price in pence	Normal price in pence	Theoretical price in pence
1	2	3	4	5	6	7	8
1892	6,717	— 2,321	7,878	—	4·49	4·34	—
1893	7,527	+ 810	7,122	10·28	4·20	4·34	4·04

1901	10,701	+ 276	10,563	2·78	4·62	4·93	5·12
1902	10,758	+ 57	10,730	0·54	5·12	4·87	4·59
1903	10,124	— 634	10,441	5·90	6·77	5·94	5·41
1904	13,557	+ 3,433	11,840	32·88	4·84	5·81	4·82
1905	11,320	— 2,237	12,438	18·89	5·83	5·33	5·94
1906	13,550	+ 2,230	12,435	17·93	5·77	5·80	4·87
1907	11,582	— 1,968	12,566	15·83	5·98	5·87	6·70
1908	13,829	+ 2,247	12,706	18·07	5·19	5·58	4·92
1909	10,651	— 3,178	12,240	25·01	7·38	6·28	6·59
1910	12,132	+ 1,481	11,392	22·10	7·77	7·57	5·99
1911	16,043	+ 3,911	14,087	34·33	5·94	6·85	5·17
1912	14,129	— 1,914	14,086	13·59	6·59	6·26	6·87
1913	14,885	+ 756	14,507	5·01	7·18	6·88	6·28

To test the results a tabulation is made of the deviations from the tendency line of the price in each month of the 21 years, i.e., 252 prices. Of the 252 prices, 143 were above the tendency line and 109 below. The excess of the total above the line is explained by the fact that information and reports of a shortage in the harvest naturally come in earlier than in the case of an abundant harvest and therefore, action and speculation for a rise work over a longer period than for a fall.

Table III.—Fluctuations from the Tendency Line

RESULTS FOR 252 MONTHLY PRICES

$\underbrace{\hspace{12em}}_{143}$

Further analysis of the results shows that 54+46, i.e., 100 prices were within 5% of the contemporary monthly point on the tendency line. A margin of 5% can fairly be allowed in the price of any article dealt with on exchange, and Dr. Harting calls all movements within 5% of the tendency line natural fluctuations, and all beyond 5%, unnatural fluctuations. The 5% margin can be regarded as a straight line running parallel on each side of the price tendency line. To anticipate the criticism that this margin might not be a straight line but a curved one, Dr. Harting tabulated the 252 fluctuations under the individual months of the year and found that the average fluctuation was practically the same for each month. That is to say, there is no seasonal variation between the different months and the margin must be regarded as a straight line.

Unnatural fluctuations occur of course as the result of abnormal influences. Dr. Harting calls all price movements outside the boundary of natural fluctuations irregular rises and falls and the next step is to analyse such cases to see if anything can be discovered as to the duration and intensity of such movements.

Out of 124 irregular movements, 81 were irregular rises and 43 irregular falls, which again illustrates the fact that the forces making for a rise operate more frequently than those for a fall.

Table V. shows the result of the analysis of irregular rises and falls.

TABLE V.—Intensity, Duration, and Average Daily Movement of Irregular Rises

*Columns 1 and 2=64ths of a penny.

A graph based on these figures shows that the mathematical probability of such movements is greater in the case of a rise than for a fall, that is to say, the probability that a falling price will extend to a given percentage is less than in the case of a rising price, e.g., the probability of an irregular rise to the extent of 2% beyond the natural interval is 0·66, for an irregular fall of 2% it is 0·6.

The table also shows that the supposition that the higher the price the greater the average daily price increase must be is not confirmed in actual practice. But although nothing remarkable can be said of the daily movements during an irregular rise or fall, analysis of the subsequent reactions from irregular rises and falls produces some interesting results.

It is found that, of the 81 irregular rises, in 69 cases the succeeding fall directly took the price within the limits of natural fluctuations and the same occurred in 41 cases of the 43 irregular falls. That is to say, the probability that an irregular rise will be followed by an uninterrupted fall to the limits of natural fluctuation is 0·85, and for an irregular fall 0·95.

Table V. is not a complete analysis of the period but it suggests that the average daily price movement during the reaction from an irregular rise or fall tends to be of the same extent as the average daily movement during the irregular rise or fall.

Summing up the results of this statistical analysis, Dr. Harting suggests that they will be found useful in actual practice. They may help the bull speculator to calculate the probable intensity and duration of a rise, and the bear speculator to foresee the time and the lowest point of a fall. For example, if the speculator is dealing with a fall following an irregular rise, he can reckon that in the majority of cases it will go within the limits of the natural fluctuation from the tendency line and also that the slope of the falling movement will correspond to the slope of the preceding irregular rise. The dealer should find the results of great value. He has to avoid buying at the maximum point of a rise, as he does not know when the price will be reached again. By the aid of the probability curve he can calculate beforehand the chance of finding a purchaser as the result of a further expected rise. If the probability of a further rise is very small he would do better to postpone purchasing until the inevitable fall after the rise and with the

TABLE VI. (xi. in original)

Rising Prices				Succeeding Fall		
Year	Rise in Points	Duration of Rise	Average Daily Rise	Fall in Points	Duration of Fall	Average Daily Fall
1897	18/64	18	1/64	70/64	80	1/64
1900	72/64	36	2/64	47/64	24	2/64
	142/64	56	3/64	148/64	42	4/64
1902	22/64	23	1/64	32/64	40	1/64
1904	41	7	6	48	7	7
1908	34	13	3	40	13	3
Falling Prices				**Succeeding Rise**		
Year	Fall in Points	Duration of Fall	Average Daily Fall	Rise in Points	Duration of Rise	Average Daily Rise
1898	26/64	72	0·4/64	26/64	96	0·3/64
1901	56/64	51	1/64	37/64	39	1/64
	56/64	62	1/64	32/64	34	1/64

help of the above calculations he can approximately reckon the level to which the price will drop. He can also calculate the time when the lowest point will be reached and in the meantime he can make his dispositions with much greater ease and certainty; an inestimable advantage from the commercial point of view.

Supposing, however, that he has been left with a stock after the price has commenced to fall. When can he expect to cover his loss ? He cannot hold the stock until the price is again reached since this costs too much in interest for capital outlay. The usual method of equalising matters is to purchase at a subsequently lower price and sell if possible at a middle price. This method of covering losses is dealt with in an investigation designed to answer the question—"Within what period will a certain price be again reached?" Dr. Harting has tabulated imaginary transactions at the highest price for each week of the 22 years and the length of time that elapsed in each case, before the price was again reached and the transaction could be completed without loss. Since in the case of rising prices the position is covered within a few days, Dr. Harting has ignored all periods less than one month.

The results for the 1,144 transactions involved are given in Table VII.

It will be seen that practically all transactions were covered within 18 months; in other words, apart from exceptionally high prices, it may be expected that any price will be reached again within 18 months.

Some explanation is needed of the fact that a price not touched by the fluctuations during a year should nevertheless be reached within 18 months. Dr. Harting's explanation is that if it is true that price is a function of the harves total it is also true that the harvest is a function of the price.

High prices make for increased harvest in the following season and *vice versa*. This might suggest that the harvest total is directly influenced by an increase or reduction of the acreage and cultivation. In this case the curves for harvest results and acreage under cultivation should show proportional movements. This correspondence does not appear on a chart except in times of extraordinary prices, and Dr. Harting suggests that the harvest total is influenced by more or less extensive cultivation on the part of the grower. High prices enable and encourage the grower to give more attention to the plant, to expend more on fertilisers, &c., and so to obtain an increased yield on the same area. That is to say, correspondence of movement is rather between yield per acre and harvest total and a graph of the movements of these two factors shows this to be the case. Of course, this theory does not explain everything, since the harvest is influenced by other factors. The weather during sowing and harvest time, or pests may

TABLE VII. (xii. in original)

DISTRIBUTION OF IMAGINARY TRANSACTIONS ACCORDING TO LENGTH OF COVERING PERIOD

Duration in Months	No. of Transactions Covered	% of Total Transactions	Duration in Months	No. of Transactions Covered	% of Total Transactions
1	671	59	23	—	—
2	127	70	24	3	95

21	5	94	81	4	100
22	4	95	82	4	100

completely change the situation. In the years 1921-23 in spite of a record area under cultivation, the depredations of the boll-weevil resulted in a lower yield than in any of the previous ten years. Nevertheless it still remains true that 18 months is the extreme limit for the duration of a covering transaction. If we buy low the rise will certainly occur within the next year; if we buy high a falling movement will occur in the next twelve months, giving place to a rising movement which will reach the purchase price within eighteen months. In practice, of course, the long term transactions will not occur as frequently as in theory. The maximum result in risk-covering transactions will arise if stock is bought at the minimum point of fall. The statistical results enable us to estimate approximately the duration of a fall and there is no necessity to hold on to stocks bought at a high price. These can be marketed as soon as the fall sets in and interest saved on the capital, which can be employed in some other productive way until the calculated moment when prices will begin to turn upwards.

[In a subsequent issue Dr. Harting's analysis for the years 1913 onwards will be discussed—EDITOR.]

National Safety Council, Chicago, U.S.A.

We have received a most interesting set of papers from this Council and commend them to the attention of all mill men. Membership of the organisation is open to firms who subscribe according to the number of employees; for 600 to 3,000 operatives the scale ranges from 60 to 100 dollars. In return, the Council supplies posters, lantern slides, films, pamphlets on safe practices, a magazine, and advice. There is a special textile section which also holds meetings. The illustrated notes on "Safe Practices" are eminently reasonable and the warning posters are perfectly clear without being crude. We must confess that the American National Safety Council appears to be much more closely acquainted with the Textile Industries than any similar organisation. —J.C.W.

THE JOURNAL OF THE
TEXTILE INSTITUTE

Vol. XVII AUGUST 1926 No. 8

PROCEEDINGS

London Section

Exhibition at Institute's London Rooms, in Bloomsbury Square, of Fabrics woven in Bradford Technical College under Bradford Textile Society's Prize Scheme, 23rd and 24th June 1926.

The chief objects of this exhibition were, firstly to illustrate the type of work being conducted by the Bradford Textile Society and the Bradford Technical College to develop colour and design as applied to woven fabrics, and secondly to obtain from London buyers of textiles, suggestions and constructive criticism so as to stimulate this section of work to a higher standard of attainment. The fabrics displayed were the results of students' experiments, produced under the Bradford Textile Society's Prize Scheme, and not the results of work of designers with industrial and factory experience. Of the 280 fabrics displayed, of which no two were alike in design and colouring, fully 60% were produced by young men who had not been employed in a weaving factory, but who, over the age of 16 years, had left a secondary, grammar or public school, and entered upon a three year course of full-time study in cloth manufacture at the Bradford Technical College. The objects of the scheme were to encourage experiments in new combinations of materials, the production of new effects due to twist and unusual structure of yarn, and to foster improvements in colour, design, and structure. The possibilities of artificial silk were illustrated by combinations of viscose and "Celanese" artificial silk, and also by combinations of artificial silk with wool, cotton, and pure silk. More than 20 various combinations, including piece-dyed two-colour effects, in these materials were displayed. One cloth, which compared very favourably with the best French fabrics, had a soft, full handle and light weight (5 ozs. per yard, 54 in. wide). This cloth was much admired. The Exhibition was visited by Representatives of the Board of Trade, Board of Education, Department of Overseas Trade, F.B.I., Drapers' Chamber of Trade, the National Federation of Launderers, London University, The Incorporated Association of Retail Distributors, and various London wholesale, retail, and shipping houses. Criticism on the whole was distinctly favourable and considerably more encouragement was offered by trade buyers than at the 1925 Exhibition. Below are a few examples of actual trade criticism—

In most cases these goods will appeal very much to the public.

You have got on to the softer touch, and away from the hardness and brittleness of a few years ago.

I like that clean slippery feel.

You have improved wonderfully in the touch and softness of artificial silk.

That is "Frenchy" in design.

What we want is effect; wearing quality has very little value, and more weight is no good.

I much prefer the botany cloths blended with artificial silk. The Botany cloths show no advance but here (artificial silk weft) and there is a novelty and it is definitely better for the market.

This is a distinct improvement on your last year's show.

One of your best cloths is that soft uncreasable spongecloth effect.

The construction of the cloths is excellent but the artistic side is weak.

This is the softest Bradford fabric I have ever handled.

It is lovely stuff but not a selling proposition in this country; there is nothing here I should feel like buying. From an educational point of view it is wonderful.

Bradford has done very much better lately; you are getting a softer handle. We have been hammering at you all the time about it.

Bradford has still got to learn a lot about handle; that goes a long way. The touch is everything.

People like all-wool cloths. If you say there is cotton in a cloth they won't have it. They don't understand what Botany really is, but the name goes a long way in selling.

Such Exhibitions without any prices being given would stimulate interest; the public are not educated to what is British.

The artificial silk introduced with wool gives the wool a much brighter appearance.

You would hardly credit these were Bradford goods.

I think you have nearly got the exact French thing; it is up to the tone, and the taste and the feel of to-day in women's dress.

The Bradford Textile Society is to be congratulated on inspiring the young men in the wool trade to produce such smart fabrics.

Professor E. Midgley, of Bradford Technical College, and Mr. Henry Binns, Hon. Secretary of Bradford Textile Society, were in attendance at the Exhibition and took note of the criticism offered.

VISIT TO HOSIERY MANUFACTURERS

On June 10th a party of members of the London Section of the Institute spent a very interesting and instructive afternoon in a visit to the works of Messrs. Dix, Watson & Co. Ltd., knitted goods manufacturers, of Alperton, Middlesex. After a hearty welcome by the Managing Director, the Works' Manager conducted the visitors on a tour through the factory. Opportunity was given to inspect each process from the winding of yarn to the finishing of the made-up garment. At the winding frames great interest was expressed at the variety of colours and of types of yarns employed. The jacquard machines, as used in connection with knitting, also attracted a good deal of attention and the visitors greatly admired the designs produced. They also noted with interest how many varied designs were produced by comparatively simple mechanism, some indeed so little complicated that the operator was able to memorise the design and subsequently adjust the machine during the knitting process so as to obtain the desired effect without further reference to his card. The visitors later passed through departments where seaming, buttonholing, teasing, calendering, and steam pressing were in progress and also viewed several specimens of made-up and finished garments. After the tour, the party was entertained to tea by the Directors of the firm, to whom a cordial expression of gratitude was tendered.

NOTES AND NOTICES

The Institute's Annual Conference

Postponed in consequence of the general strike, the Annual Conference of our Institute, originally fixed to take place at Buxton during Whit-week, is now being convened for the third week in October. It is hoped that the rearrangement of the fixture will not involve any material departure from the original programme. Sir William Bragg, K.B.E., has kindly accepted re-invitation to contribute the Annual Mather Lecture of the Institute and has engaged to attend at Buxton for

the purpose on the morning of Thursday the 21st October. On the Friday morning (22nd) it is expected that the papers by Mr. J. A. Robertson, M.I.E.E., M.I.Mech.E. (on Centralised Electricity Production), and by Mr. Percy Bean, F.C.S., M.Ph.S. (on the subject of Sizing), will be contributed in accordance with the programme previously presented. Printed programme and attendance form are in course of preparation for posting to members. Meantime, members are urged to make note of the dates of the fixture—at Buxton, Wednesday, 20th October, to Friday, 22nd October, inclusive. The proceedings will commence on the Wednesday evening with a reception. After the Conference on the Thursday morning, it is hoped to arrange for a visit to works at Macclesfield as originally planned.

Section Meetings of the Institute

Arising out of a recent meeting of the Lancashire Section Committee of the Institute, at which the possibility of availability of a paper of interest to the knitting industry was mentioned, it was agreed that endeavour be made to provide for such a paper to be presented at a meeting at Leicester—to be held under joint auspices of the Institute and the Leicester Textile Society. It is now proposed to hold the meeting at Leicester during the period of the Exhibition of Textile Machinery, and the date contemplated is the 16th October (Friday). Mr. Frank Nasmith has kindly promised to provide accommodation for the holding of the meeting and members of the Institute will be given opportunity to inspect the exhibition. Further particulars will be issued later. The paper at Leicester will be contributed by Mr. Herman S. Bell, of Nottingham, who will deal with the subject of "Thread Take-up in the Seaming of Knitted Fabrics." Mr. John T. Stokes, the Hon. Secretary of the Leicester Textile Society, has notified acceptance of the proposal to promote the meeting under joint auspices.

Textile Institute Diplomas: Fellowships and Associateships

Since the publication, in our July issue, of the list of additional names of members elected to the Fellowships or Associateships of the Institute, the following elections have been completed—

FELLOWS

BARBER-LOMAX, Joshua Arthur (Bolton).
CHADWICK, Arthur (Rochdale).
HUEBNER, Julius (Cheadle Hulme).
KERFOOT, James (Sidcup).
PADGETT, Charles (Bradford).

ASSOCIATES

BUTTERWORTH, Ernest (Stockport).
CRESSWELL, Albert (Blackburn).
DEARNALEY, Alfred (Hadfield).
GEE, Percy Herbert (Huddersfield).
HEYWOOD, William (Bombay).
JONES, George (Blackburn).
LEES, Robert (Audenshaw, near Manchester)
POMFRET, Harry (Rishton, near Blackburn).
ROTH, Alfred Bernard (Rochdale).
ROTHWELL, Herbert Theaker (Huddersfield).
SMITH, John (Walkden, near Manchester).
SPENCER, Arnold Kingsley Norman (Bradford).
WRIGHT, Robert Harcourt (Gatley, near Stockport).
WYKES, Alfred Launcelot (Leicester).

REVIEWS

Die Verwertung der Zellstoff-Ablaugen. By Dr. A. Schrohe; published by Otto Elsner Verlagsgesellschaft, Berlin (140 pp. and Index. 2 marks).

This book consists of abridgements of patent specifications filed since 1912, on the application of the waste liquors obtained during the manufacture of wood pulp. German, American, English, French, Austrian, Swedish, and Swiss patents are dealt with, the whole being classified in Section A, according to the particular uses for which the products are applied. These uses include the manufacture of alcohol, finishing materials, winding materials, fuels, manures, tanning materials, and others. In Section B the same patent specifications are arranged in the order of dates of application. The book is particularly useful to those inventors who are interested in securing patents on the subjects dealt with. —W.H.

Technologie der Textilveredelung. By Dr. P. Heermann; published by Julius Springer, Berlin (632 pp. and index; 33 marks).

This book is a very useful treatise on bleaching, dyeing, and finishing of textiles. In the introduction figures for the world production of textiles are given which would be more useful if brought up to date. The first section deals with the textile fibres. An outline of the research work done in cellulose up to 1925, including the X-ray work of Herzog and others is given. The physical and chemical properties of cotton, kapok, vegetable silk, linen, hemp, jute, and ramie are dealt with, together with statistics of production. Wool, animal hairs such as camel hair, wild and cultivated silks, and also mussel or sea-silk are dealt with in a similar manner. The various forms of artificial silk are considered and figures for world production up to 1924 are given. A chapter is devoted to the consideration of the properties of water, its purification by filtration and chemical treatment by the most modern methods, with description of apparatus used and also the treatment of sewage of effluents from textile works. The chemicals used in the textile industry are then considered : acids, alkalis, salts, bleaching agents, mordants, tannins, and moth-proofing agents, soaps, oils, and finishing agents, as well as thickening agents used in printing, and finally dyestuffs, including mineral colours, natural dyestuffs, and all the artificial dyes applied in modern times. An account of the practical methods of mercerising yarns and fabrics is given, but some of the machinery illustrated is very out-of-date. The production of transparent, opalescent, and wool (philanising) effects is mentioned. A full account of all the processes used in the bleaching of cotton is given and mention is made of damages caused during bleaching. The bleaching of linen, hemp, jute, and ramie finds mention. A chapter is devoted to the scouring, bleaching, washing, carbonising, and milling or felting of wool; a sketch being given in proof of the scale theory of felting which the reviewer regards as obsolete. The degumming and bleaching of silk is described, as well as the boiling and bleaching of mixed goods. A section of the book is devoted to dyeing and deals with the theory of colour, colour harmony, and colour mixing according to Ostwald's theory, of which an account is given with diagrams. The various methods of dyeing are then described, including basic, acid, and mordant colours on animal fibres; and direct, basic, sulphide, mordant, and vat colours, as well as diazo colours, on cotton and artificial silk. Various types of apparatus are illustrated for dyeing and drying. The methods of weighting silk are considered as well as the after-treatment of dyed and weighted silk. The dyeing of leather, fur, feathers, horn, straw, wool, flowers, grasses, and paper are dealt with. A section is devoted to the printing of fabrics of wool, cotton, and silk; another to the finishing of cotton, linen, wool, and silk, in fabrics and also in yarn; another also to the waterproofing and rubbing of fabrics and to the fireproofing of fabrics. This book is invaluable to those engaged in the industries to which it refers. —W.H.

GENERAL ITEMS AND REPORTS

"Dating of Patents" Committee

A Committee has been appointed by the Board of Trade to consider whether any, and, if so, what change is desirable in the practice of—

(*a*) Dating patents, applied for under Section 91 of the Patents Acts, as of the date of application in the foreign state; and

(*b*) Dating patents granted upon ordinary applications as of the date of application in the United Kingdom.

The main question which the Committee has to examine is whether this practice should be continued or whether patents granted upon applications made under Section 91 should bear some later date, such as the date of application in this country, or the date of grant of the patent, while still giving the applicant the priority as regards inventorship which must be given to him under international arrangements.

The Committee will be glad to receive suggestions or representations upon the matters covered by their terms of reference. In considering the questions involved, the Committee desires that due regard should be paid to all the interests involved, i.e., the interests of inventors, manufacturers, consumers, and the public generally. Communications should be addressed to the Secretary to the Committee, Mr. B. G. Crewe, The Patent Office, 25 Southampton Buildings, London, W.C.2.

British Association Meeting at Oxford ; 1926

The Hygroscopic Properties of Colloidal Fibres and their Relation to Technical Processes

Messrs. S. G. Barker, H. R. Hirst, and A. T. King, of the British Research Association for the Woollen and Worsted Industries, at a meeting of Section A of the British Association held on 10th August presented a paper under the above title in the course of which the theory of elasticity of colloidal fibres was developed, and it was shown that wool fibres possess the usual characteristics of colloids. Wool structure can apparently be represented by an elastic framework filled with a viscous medium. The effect of moisture absorption on the viscous phase was discussed, and it was stated that wool is a perfectly elastic material and makes a complete recovery from strain even up to its breaking point. The effect of moisture on thermal and electrical conductivity was discussed. In the former case it was shown that the increase in thermal conductivity of dry material for an increase of moisture content of 1% of the dry weight, ranges from 0·0000017 to 0·000002 for wool. The electrical conductivity is shown to increase with moisture content and it is noted that perfectly dry fibres are non-conducting.

Following an outline of the distinctive regain characteristics of wool as compared with other fibres, the relation between density and regain was discussed and an expression devised connecting apparent density with regain. Reference was made to the regain and swelling exhibited by wool with other liquids than water, especially with ethyl and methyl alcohols, and to the significance of this in arriving at the true density of wool by displacement methods, this value, 1·30, being obtained in benzene in which wool exhibits no regain or swelling. The variation of the true density and the apparent density in water, with regain was shown graphically A mathematical relation between the apparent specific volume, swelling and sorption (or liquid regain) in any liquid sorbed by wool was derived, which in the case of water, gave a calculated swelling in close agreement with the observed values. Reference was made incidentally to the analogous behaviour of gelatine.

The mechanism of the heat of wetting was discussed in relation to regain, swelling, and rate of evaporation, and the several theories of solid solution, liquid film compression, and surface area due to porosity were referred to. The evidence for porosity was discussed in detail and the conclusion was reached that the various phenomena are explained by assuming the keratin substance of wool to be of the type of structure observed in dried gelatin jellies, rather than to the surface area or due to any grosser heterogeneous structure such as would be involved in the individual cells of scales or cortex, or the easily observable pores found by Mark.

The swelling of wool fibres has been investigated by the authors, and the results of such swelling in air of various relative humidities and in water, alkalis,

acids, and organic liquids recorded. The accompanying physical changes due to sorption of moisture which may be described as variation in plasticity or pliability, were shown to be of great importance in technical processes of the wool industry. The significance of the hygroscopic characteristics of wool fibres with regard to manufacturing processes was also described.

Investigation of the fading of worsted cloths dyed with typical dyes of different chemical constitution, exposed to sunlight and air in India and at home, shows that there is a relation between loss of colour and the amount of moisture in the atmosphere. The sensitiveness of wool to bacterial damage has also been investigated, and shown to reach a maximum at the point of extreme saturation with moisture. In this connection reference is made to the damage caused by uneven trade conditioning.

The Colour Users' Association

Addressing the seventh annual meeting of the above Association on Tuesday, 27th July, Mr. H. Sutcliffe Smith, the Chairman, said that he thought the work done by the Association during the past year had proved extremely useful to all colour users and he thanked the Council, the staff, and all members for their share in the work accomplished. He then proceeded to review the work of the various standing Committees of the Association, and, referring to the Dyestuffs Advisory Licensing Committee, thanked the representatives of the Colour Users' Association for their services on this important Committee. Some idea of the magnitude of the work involved might, he thought, be gathered from a consideration of the figures of the Board of Trade covering licenses granted during the five years 1921 to 1925. In 1921 licenses covering an importation of nearly 3,000,000 lb. of dyestuffs valued at over one million sterling had been granted, while in 1925 the poundage had increased to 3¼ million pounds, though for obvious reasons the value had dropped. He suggested that the importation of approximately 1,500 tons of dyewares in 1925 compared with a pre-war importation of 18,390 tons, indicated considerable progress on the part of British makers, but suggested that there still remained a wide field of enterprise which should have the very close consideration and immediate attention of dyestuffs makers. "Unless British makers," said Mr. Smith, "make the fullest use of the remaining period of the Dyestuffs (Import Regulation) Act and are able to meet the complete demands of British users, particularly in the better types of vat colours and the specialities now offered by foreign makers, they will be in a serious position when the British market is eventually exposed to open competition." Turning to the work of the Joint Technical Committee of the C.U.A., Mr. Smith said that in his opinion there was one particular question in regard to which the services of this Committee would be of great assistance. He was convinced that something should be done to reduce the number of brands of dyestuffs now on the market. Hundreds of dyestuffs were produced yearly, of which only a few pounds had been sold. This was wasteful and uneconomical and if users would concentrate on fewer types for which they could give larger orders, makers would have a chance to produce economically and quote lower prices. Mr. Smith, considering the requisitioning of reparation colour from Germany by the United Kingdom, pointed out that no colour had come into the country under this head and that of the stock of colour on hand at the end of last year only about 450 tons remained to be disposed of. Reparation colour, he said, was still being imported by France, Italy, and Belgium, but as such colours were now being sold on a commercial basis no undue advantage was being given to the consumers in those countries. Continuing, the Chairman again drew attention to the great developments in the chemical industries achieved since his previous address. More particularly had these developments taken place in Germany and they were characterised by consolidation of interest, research on wide lines, and production in big units. He was satisfied, however, that there was evidence of continuous progress in the British dyemaking industry, but he wished to emphasise the vital importance of fundamental research and to point out that there was also a wide field for research into the improvement of technical methods. The Dyestuffs Industry Development Committee, the British Dyestuffs Corporation, Ltd., and the Interessen Gemeinschaft with its distributing company in this country were then dealt with by Mr. Smith, who concluded his address with comments on the observations of the deputation from the Association to France, Italy, Belgium, and Germany to consider dyestuff prices in those countries, and said that a complete report from the deputation would shortly be ready.

THE JOURNAL OF THE
TEXTILE INSTITUTE

Vol. XVII SEPTEMBER 1926 No. 9

PROCEEDINGS

LUNCHEON MEETING OF U.S.A. MEMBERS OF THE TEXTILE INSTITUTE

The following report of a meeting of U.S.A. Members of the Institute held at Boston, Mass., on the 5th August, is communicated by Mr. C. H. Clark, of Boston.

"The first meeting in this country to be held by members of The Textile Institute, England, took the form of an informal luncheon to Mr. W. E. Morton, Professor of Textiles at the College of Technology, Manchester, England, who has been here for several weeks on a visit to textile mills, and was held at the Exchange Club, 5th August, the following members and guests of the Institute being present. *Members*—Professor W. E. Morton, Manchester, England; Franklin W. Hobbs, Boston, Mass.; E. E. Blake, Biddeford, Me.; C. H. Clark, Boston, Mass.; F. J. Hoxie, Boston, Mass.; Edwin H. Marble, Worcester, Mass.; C. E. Mead, Boston, Mass.; Brackett Parsons, Boston, Mass. *Guests*—Russell T. Fisher, Secretary National Association of Cotton Manufacturers, Boston, Mass.; Clarence Hutton, *Textile World*, Boston, Mass.; Henry G. Lord, *Textile World*, Boston, Mass.; James McDowell, Somerville, Mass.

Mr. Franklin W. Hobbs, President of the National Association of Wool Manufacturers, and of the Arlington Mills, Lawrence, Mass., kindly consented to preside, and Mr. C. H. Clark, editor of *Textile World*, acted as secretary. Several of the local members regretted that other engagements prevented their being present, these including George L. Gilmore, of K. L. Gilmore & Co., Somerville, Mass.; E. D. Walen, Pacific Mills, Lawrence, Mass.; and F. W. Reynolds, Lockewood Greene & Co., Boston, Mass.

Professor Morton, in his talk, dwelt particularly upon the work of the Textile Institute, and in a somewhat less detailed manner on the work of the British Cotton Research Association with which he was formerly associated. He made it clear that in this country there was no exact counterpart of the Textile Institute both with reference to its membership and to its work, as the Textile Institute covered all branches of the industry and now was licensed under a Royal Charter to grant Fellowships and Associateships to members qualifying therefor. He also made it plain that the Textile Institute was not engaged directly or indirectly in research work, but that the source of most research articles published in the *Journal of the Textile Institute* was the various Government-aided British Textile Research Associations. He expressed the hope that the membership of the Institute in the U.S.A. might be so broadened as to make available to the parent body and for publication in the *Journal* of the Institute more reports and papers relating to textile research and practical and technical textile development.

There was a very general and lengthy discussion of the points raised by Professor Morton and with regard to the advisability of establishing a branch of The Textile Institute or some co-operating organisation in that country. It was the consensus of opinion that detailed discussion of this subject be deferred until a later general meeting of the U.S. members.

not all, of the four fixtures last-named, will be in association with local textile societies. The London Section, it is expected, will have announcements to make at an early date regarding its programme. Another meeting which may be here referred to is that which has been arranged to be held at Leicester at 4.30 p.m. on the 15th October. The fixture will provide opportunity for an inspection of the Textile Machinery Exhibition at Leicester as well as attendance, in the exhibition buildings, at a lecture to be given by Mr. Herman S. Bell (Nottingham) on "Thread Take-up in the Seaming of Knitted Fabrics." The Leicester Textile Society will take part in the meeting, and Mr. T. Fielding Johnson J.P. will preside. Members of the Institute in the Midland districts will receive notices of the meeting, but members generally who would like to attend and visit the Exhibition on the day in question should write the General Secretary of the Institute for ticket, and for voucher for securing return railway ticket at reduced fare.

Design and Structure of Fabrics

In connection with the Institute's Crompton Prize Scheme for students at Technical Colleges and Schools, the Committee has recently given serious consideration to various suggestions with regard to modifications of the scheme of competition. Mr. J. E. Dalton presented a statement to the Committee explaining the attitude towards, and criticism of, the scheme in various districts. One objection was that, at present, the scheme allowed students passing Section A of City and Guilds to compete in the same year. Further, it did not appear that the scheme of competition definitely encouraged the individual who approached design from the standpoint of the artist. The Committee decided to convene a conference of members of the Committee, and representatives of colleges and schools, and of various organisations associated with both employers and employed. The conference was held on the afternoon of Saturday, 11th September, when over 20 persons were in attendance. A prolonged discussion took place and the scheme was considered in the fullest detail, the meeting lasting for three hours. There was fairly general agreement that some effort should be made by the Committee to secure further limitation with regard to the number of specimens to be submitted by competitors. The Committee were also asked to define clearly whether the work of competitors was to be considered as a recognition of effort during an ordinary training course or work of a special, advanced, and original character. It was also agreed that the various groups of fabrics to be covered by competitors should be revised, and commercial terms employed for cloth description as far as possible. Perhaps the most important recommendation of the conference was that special consideration should be given to the question of division of competitors—Evening Students, Day Students, and Art Students—but the Chairman (Mr. John Crompton) pointed out that a division on lines suggested would require provision of additional prize money. It is expected that a meeting of the Committee will take place at an early date to give full consideration to the views ventilated at the conference.

Conference of Representatives of Textile Societies, &c.

A few years ago, this Institute sought to promote the increased usefulness of textile societies and kindred organisations by bringing together representatives of these bodies for discussion of matters of mutual interest. The result has been that, at least annually, the representatives meet at some suitable textile centre, and the Textile Institute has contributed to the movement by undertaking the secretarial duties. The next conference is fixed to take place at Blackburn Technical College on the afternoon of Saturday, the 9th October, by invitation of the Blackburn Textile Society and the National Federation of Textile Works Managers' Associations. The programme announces a reception at 3.15 by Mr. Chas. Tate, President of the Blackburn Textile Society, and Mr. J. H. Dawson, President of the Federation already named; inspection of an exhibition of designs

and cloths produced in the college; and inspection of the Textile Department and the Textile Chemistry Depratment of the College. Tea will be provided in the College by the organisations concerned in the invitation to visit Blackburn, and afterwards there will be a discussion on "The Work of Textile Societies and its Relation to Technical Education generally."

Publications added to the Institute Library

July to September 1926

Books

Transactions of the Manchester Association of Engineers. 10 volumes, from 1906 to 1914. Presented by the Hon. Treasurer, T. Fletcher Robinson Esq.
Hosiery Yarns and Fabrics. J. Chamberlain. Official Text Book, Leicester College of Technology.
Handbook of Weaving and Manufacturing. H. Greenwood (Pitman & Sons Ltd.).
Testing of Yarns and Fabrics. H. P. Curtis (Pitman & Sons).
Wärmewirtchaft in der Textilindustrie. F. Möller (Verlag T. Steinkopff).

Pamphlets

REVIEWS

Textile Bleaching, Dyeing, Printing, and Finishing Machinery. By A. J. Hall; published by Ernest Benn, Ltd., London (317 pages and index; 50s. net).
This book, as its name implies, deals with the description of the machinery used for bleaching, dyeing, printing, and finishing of yarns and fabrics of cotton, wool, and silk and is profusely illustrated, there being upwards of 300 illustrations mainly from machine-maker's catalogues. A buyers' guide is given at the end. The book should fulfil many requirements; it will, for instance, save textile students a lot of time in sketching in their note books the machinery used in the industry and will serve to show those already familiar with the industry other types of machines than those they are familiar with. The work is mainly descriptive and does not assist a newcomer in deciding which of the various types of machine described is most efficient for their particular purpose. In view of the fact that the book also contains advertisements by the various firms whose machines are illustrated, the author ought perhaps to be complimented on avoiding favouritism. The book would have gained value by the inclusion of several modern machines, for example, the cylinder drying machine of Dod Bros., Manchester; the continuous hank drying machines of A. N. Marr, of Leeds; several other forms of hank mercerising machines used in the manufacture of book cloth, leather cloth, and rubbered fabrics; and Brandwood's bleaching and dyeing machinery. In fact, a book of this kind needs to be very much up-to-date to be of real advantage to those familiar with the industry. The printing, binding, and general get-up of the book is well in keeping with the standard set by its publishers and should find a ready demand. —W.H.

Wärmewirtschaft in der Textilindustrie. By Fedor Möller. Published by Theodor Steinkopff. Dresden & Leipzig, 1926 (108 pp. and Index).
This little monograph dealing with fuel economy in the textile industry should be very opportune at the present time. It gives a clear account of the various causes of loss of heat in spinning, weaving, dyeing, printing, bleaching, and finishing, and discusses the various remedies. The course of heat supply is followed from the boiler house onwards and each room or section is dealt with in considerable detail. At each stage the amount of heat utilised and the amount lost is worked-out numerically, often a balance sheet drawn up, and the pros and cons of alternate methods of using the heat discussed. From the figures given it would be easy, by making the necessary changes, to calculate the efficiency of any textile factory as far as fuel is concerned. The author lays stress on the necessity for rigid control if efficiency is to be maintained. The numerous diagrams help one to visualise the extent to which heat is lost in the various processes; unfortunately they lose value by being reproduced on too small a scale. The book ends with an extensive bibliography of the literature, which will be helpful to anyone wishing to pursue the subject further. —R.G.

Liverpool Cotton Annual, 1926. Compiled by Charles Rigby. Published by Robinson and Rigby, Liverpool (56 pages, 2s. net.).
This is an attractively produced newcomer among annual publications, and is an attempt, according to the "Editor's Note" to provide a reference book that will demonstrate "Liverpool's pre-eminence as a cotton market," and "convey an illuminating vision of the intense human energies which enter into the daily life of the cotton exchange." From the point of view of an annual publication on its first appearance it is perhaps rather harsh to suggest that probably none of the contents of this annual, with the exception of the statistics, will require repetition. At the same time it must be admitted that the articles included, from the historical notes with which the annual opens to the abstract of a lecture on research in the cotton industry, are all interesting and well worthy of record in connection with Liverpool and its cotton trade. A similar series of articles in subsequent "Annuals" dealing with other phases of the cotton activities of Merseyside would certainly furnish something new in Year Books, and the series would eventually acquire definite historical value. If this is the compiler's idea it seems to be a good one. A word of commendation must be passed for the printer's share in the work, but more care should have been taken in proof reading as several typographical errors have been missed. The annual is well worth the price asked. —H.L.R.

Air Conditioning in Textile Mills. Edited by Albert W. Thompson. Published by the Parks-Cramer Company, Boston (495 pp., price $5.00).

This is a work compiled under the auspices of an American company who specialise in air conditioning in textile and other factories. One does not expect, of course, in such a book the critical impartiality of an ordinary text book, but the present work does not display any displeasing crudity of advertisement, and gives the general impression that it is a carefully compiled and sound semi-popular treatise on the subject of humidity in relation to textile manufacturing.

The book may be divided into the following main divisions: Chapters I. and II., dealing with the effect of humidity on the properties of the various textile fibres; Chapters III., IV., V., and VI. dealing with the most favourable conditions for processing; Chapter VII., dealing with regain testing and standards, tensile testing, and regain equilibrium between textile materials and the atmosphere; Chapters VIII., IX., and X. with humidifying installations and the underlying scientific principles, and Chapters XII. and XIII. respectively with the effect of humidification on health, and the effect of external weather conditions on the factory atmosphere.

The book covers a wide range, every aspect of the subject being discussed, and it may be admitted at once that it is a distinct achievement to recognise every aspect of such a far-branching subject, so that the compilers are to be congratulated on the mere table of contents. When one comes to examine the work in detail, it is evident that it is very unequal. The more propagandist portions are extremely well written and avoid the error of exaggeration. The sections dealing with textile technique are good, especially when one considers the difficulty of collecting reliable information. The scientific side of atmospheric humidity is admirably treated, being clear, accurate, and displaying considerable critical ability (though the writer is rather too severe on the ordinary wet and dry bulb hygrometer, which in its proper sphere is a very useful instrument). The weakest section is Chapter VII. dealing with regain from a scientific point of view. No reference is made in it to the work done under the auspices of the British textile research associations, though much of it is in direct opposition to views held previously. The general level of this portion of the book is perhaps best illustrated by the extraordinary remark on p. 213: "The general laws relating to regain in textiles as deduced from the research of Hartshorne and his predecessors are now generally accepted. . . ." The part of Chapter VII. dealing with tensile testing is more satisfactory, though the various data are imperfectly correlated with each other and with the chapter on the effect of humidity on the single fibres.

Chapters III., IV., V., and VI. are evidently founded on American practice, which appears on the whole to agree with English practice when allowance is made for climatic differences. Two recommendations given in Chapter IV., however, appear strange. Humidifying a combing shed to 70% relative humidity is surely unnecessary, not to say undesirable. On the other hand, 65 to 75% is undoubtedly low for French drawing. —S.A.S.

GENERAL ITEMS AND REPORTS

Royal Society of Arts; Competition of Industrial Design, 1926

The report of the third year of this annual competition has been received, and it is noteworthy that on the whole the judges consider that the standard of excellence is very decidedly higher than on the two former occasions. The Council records that they have received assurances from many quarters that the competition has aroused the greatest interest amongst students generally, and that in some schools work is being carried on with a zeal and earnestness not known before. That the interest in this scheme is wide-spread may be judged from the list of Schools of Art from which competitors were entered. Schools as far apart as Belfast and Bournemouth or Kirkcaldy and Ipswich provided entrants, while the name of the Technical College, Wellington, New Zealand, is also included. Apart from the interest of the students and schools of art, evidence is offered in the report that the various industries concerned also look upon the scheme with favour, and a large number of firms have offered

special prizes for particular subjects. Altogether, more than £1,700 has been distributed in prizes during the last three years. An exhibition of specimens selected from among those entered for the competition was held in the Upper East Gallery in the Imperial Institute from 31st July to 31st August, and served a very useful purpose in bringing the work of the Royal Society of Arts in this particular direction before the public. Of particular interest is the section of the competition devoted to textiles, which is controlled by a strong and representative committee under the chairmanship of Sir Frank Warner K.B.E. Entries in this section may be made under one of six alternative sub-sections, which are as follows—(1) Floor coverings; (2) Woven fabrics for furniture and decoration; (3) Printed fabrics for furniture and decoration; (4) Printed and woven fabrics for dress goods, handkerchiefs, ties, mufflers &c.; (5) Machine-made lace and embroidery; and (6) Miscellaneous, including hand-made lace, cushion squares, batiks &c. The judges' reports on these sub-sections should be of value to those whose business it is to advise and train student-entrants for future competitions. For example, it is recorded that many of the designs submitted in sub-section (1) were on dull and stereotyped lines, and that it is regrettable that there should not be more evidence of a freshness of thought. Sub-section (2) judges report that while the level of merit is decidedly higher, some of the designs were coloured in such a manner as to indicate that the students had not visualised their designs in fabric form. The judges in this sub-section also record that in their opinion the attention of both designers and manufacturers should be called to the fact that though the present fashion is in favour of small mats for dining-room tables instead of large cloths, no designs were submitted of the former. The report on the design submitted in the dress-goods section states that it is a mistake to pay any attention to a "fashion" of a previous day, the only "fashion" worth considering being the current one. The judges also report that it was gratifying to see more economy in the use of colour than usual; charming effects being obtained in some cases by the use of only three colours. Over-elaboration is pointed out to be a mistake, and in this connection it is suggested that motifs might be more carefully considered; many designs contained enough motifs to make half-a-dozen good designs. Students should note that designs in this section should be executed in flat colour, as for printing the engraver must be able to understand clearly what is meant. In this sub-section one of the Society's Travelling Scholarships was awarded to Miss Pauline Athey, a student at the Manchester School of Art. In sub-section 5 (Machine-made lace) the report states that the designs submitted show, on the whole, an appreciation of the situation and needs of the lace industry at the present time, and records that in many cases this has been done without setting aside past tradition. As a guide to students it is pointed out that as far as possible design should show the effect of the texture itself. For instance, where the lace is intended to be white or lighter in tone than its background, an ink or pencil line on white paper does not produce the desired effect. It is interesting also to be able to record that for the benefit of those competitors whose work is approved by the judges for exhibition, a bureau of information is to be started where their names will be enrolled if they desire to obtain employment as designers. The information will be at the disposal of manufacturers, and it is hoped that both manufacturers and designers will find the bureau of service.

THE JOURNAL OF THE
TEXTILE INSTITUTE

Vol. XVII OCTOBER 1926 No. 10

PROCEEDINGS

THE COTTON TEXTILE INDUSTRY IN THE U.S.A.

The first luncheon-hour meeting of the 1926-1927 session of the Lancashire Section of the Institute was held in the Council Room, Manchester, on Friday, 24th September, when Professor W. E. Morton and Mr. H. G. Greg delivered addresses upon the information and experiences they had gained during a recent visit to the U.S.A. Mr. Frank Nasmith presided, and there was a large attendance of members.

The Chairman, in introducing the speakers to the meeting, said that the Lancashire Section was endeavouring to arrange for the giving of a number of lectures dealing with methods of textile manufacture in various foreign countries. It was also hoped there would be a lecture, before the Christmas period, by a gentleman from Kettering upon the subject of "Price Forecasting," while prior to March next there would be one by the Chadwick Trust upon "Industrial Fatigue," and a third by Sir William Himbury entitled "Raw Cotton Supply." The Lancashire Section had tried to map out a very strong programme for the year, and, from the excellent attendance upon the present occasion, it certainly appeared as though they would have a thoroughly good session. The second lecture of the session would be delivered by Capt. Sherston, and was entitled "Impressions of a Recent Visit to Italy."

Professor W. E. Morton said—In planning out our effort for to-day Mr. Greg and I decided that the best thing would be to divide the proceedings into two sections, in the first of which I should deal with the technical details of interest and that he would follow on with points of more general industrial organisation. Obviously, in five weeks' touring one can pick up quite a considerable number of extremely interesting facts, but it is only the more important of these that I shall now be able to touch upon.

Commencing with the first operations of the spinning mills, the most notable feature was the difference in opening machinery compared with what we have in this country; not in the actual machines themselves but in the quantity. The Americans have nothing like the huge combinations of opening machinery one normally sees in spinning mills in this country. They are not very fond of up-stroke beaters. They have down-stroke beaters and a scutcher and laphead, and then only one finishing scutcher. Their mixing is done by the stack method for what they consider to be medium counts and for what we consider to be fairly low counts, 36's and 40's. They have their mixing bins in separate buildings from the blowing room, and the material is conveyed by pneumatic trunks. By that means, they avoid having to pay rather high insurance premiums. The reason for the small equipment in opening may possibly be found in the type of cotton used. We expected when we went there to find the same kind of cotton one uses in this country. We asked "What is this cotton ? " They said "That is Arkansas, Texas or Memphis cotton." In some cases we saw local cotton. But it never seemed to be the same as the "Arkansas," "Texas," or "Memphis" cotton that we use in this country. The difference is possibly rather hard to describe, but it has a rather harsher, harder, and more wiry "feel," and I should imagine it would be a much more easily cleaned cotton, which may account for

the reduction possible in opening and cleaning apparatus. The "Crighton" opener was not much in favour, but we understand it is rather coming to the front. Also, we saw horizontal cleaners something like those used in the early days of cleaning machine development. Apparently, they were rather afraid to have splitting laps in the carding, because we saw in every case the cards were fitted with a device for avoiding this, which apparently overcame their difficulties. The only other point of interest in the opening and blowing was the supply of air to the fans for the scutchers Normally, they have to put a great deal of humidity into their atmosphere, and it costs them a good deal to do it, so they cannot afford in the more up-to-date mills to have this expensive humidified air drawn through the fans and out into the dust towers. In the case of two mills we found they have special ducts for drawing dust up from the scutchers and out through the fans again. In that way, they avoided withdrawing air from a mill which had been expensively humidified.

Generally speaking, the carding was good, light, and relatively slow, but the stripping devices were the "Saco-Lowell" type of stripping, which, by turning a handle, can be turned over either to the cylinder or the doffer. There is no dust thrown out into the room from the stripping processes; it is all drawn away by suction. On the whole, we do not consider it is a very effective method of stripping, though it has an advantage over the "Cook" system in that the waste is better for selling to the waste dealer. In regard to the draw frames, one very rarely observed more than two heads to the draw frames. They seem to run on the system there of cutting down the processes as much as possible, consistent with obtaining good work. I know many people think it will ruin work to cut out either a speed frame or a drawing frame, but for their purposes there must be something in it because they are eminently careful in investigating problems, in which respect they are very much more systematic than, I think, we are in this country. One point was raised by a mill engineer, I think in Greenville. He advocated the use of five ends up for drawings instead of six in order to get a better selvage. I do not know how it would apply in this country, but apparently it would have a use under their conditions. Combing we found extensively used for what we call medium counts, even as low as 30's, especially if used as hosiery yarns, although in one mill they admitted it was probably not as effective as a good carded yarn.

They have very little mule spinning as compared with ring spinning, and, on inquiry, we found that the reasons are two-fold. First, there is the difficulty in getting really skilled spinners, and, secondly, those that they had had strong unions and were causing them trouble. They will apparently sooner put up with spinning reasonably high counts on ring frames than have bother with the unions. The next thing, as I think most people know, is the saddle weighting for all top rollers of the spinning frames. Only in one mill that we saw had they middle top rollers. They are very chary of high drafts, and this particular mill were anxious to go as far as they possibly could with the existing roller arrangement. They were in the middle of their investigation, and I do not know how it worked out. Ordinarily the drafts we saw were fairly high—six to ten.

The frames are nearly always band-driven which they find pays them as they get surer work. They admit it takes rather more power but it has the advantage of surer working in starting in the early morning. We found that the warp yarns were nearly always weft built; that is to say, they had not a straight build on their bobbins. They said this gave easier readying, and there is less likelihood of the unskilled operative pulling the bobbin to pieces, while they get more on the package. I cannot believe that, because if you have the threads crossing over, as one has to have in a weft build, it is inevitable that the package must be softer. They say they get less breakages. They were using large bobbins, up to 8 or 9 inches, bigger than we have in this country at any rate. Before leaving the spinning frames one cannot help mentoning the "Saco-Lowell" spinning frame. We saw one of these. The gearing is at the opposite end to the drive.

The main shaft runs through the tin roller, and the gearing is covered in by doors which can easily be opened; not heavy cast-iron plates which have to be lifted out without much room to do so. The gears are all helical cut, and they consider they get steadier and more regular running with them.

Turning to the sizing, we observed that a very light size is generally used; in no case did we find more than 10% and it is usually about 5% to 7%. Where they were winding on for a multi-coloured warp they wound on through a reed to facilitate drawing in. In their sizing rooms the lack of steam and water was very noticeable. Usually they had huge copper hoods for drawing-off the steam, and carefully designed ducts in the floors for water. On the whole, the rooms were much cleaner than I have seen them elsewhere.

The dyeing is rather interesting. We observed in one mill the complete spinning of dyed stock; that is to say, the material is brought in in the bale, opened, and cleaned with a small amount of opening machinery, and then dyed straight away in a huge cylinder. It is then dried, and spun in the dyed form in their various stock colours. By that means, they are able to get a very level colour, and, as far as weft is concerned, they can cut out one of the preparation processes in winding. We asked if they used oil for making the stuff work rather better but they said "No." Apparently they had tried it and found it did not do any better than mere water. They have a system of spray humidifiers spraying water on to the cotton in the hopper feeder. The next thing about dyeing is the use of "Franklin" dyed yarn for weft. They wind the yarn on to packages, and have it dyed in that form, and then pirn it and use it directly on the weft. The levelling of the dyeing is not good, and it will not do for large quantities of colour, but for pin stripes and narrow stripes the mill people find it quite satisfactory and rather cheaper. In wefts we found a prevalence of chain dyeing followed by pirning on quilling frames, that is, multiple-spindle winding frames.

In the weaving room, except for drop-box looms, dobbies, and jacquards all looms were automatics. We saw two-colour automatics for weaving ordinary two-coloured ginghams, and even in the exceptions to the automatics we never saw an over-pick loom. They were all under-pick, warp-stop motions, even on the non-automatic looms. For what they consider low counts, and below them, they have steel heddles as a rule, and for finer counts the ordinary cotton heald predominated. Another interesting thing in connection with looms appears to be a movement in the South towards the use of a deeper reed, deeper dents, so that they are stronger and less liable to be bent, and, of course, thus form cracks in the cloth. Finishing and making-up are all done in the same mill. Perhaps I should have mentioned before that in every case we saw the whole of the processes from raw cotton to the finished fabric ready for sale carried out either by one mill or by a group of mills working in conjunction.

I will now turn to more general things and deal with the lay-out. First of all, there is the large amount of space available for temporary storage and for rapid internal transport. The importance of this was stressed many times by the managers, and it was evident in every department, and, in particular, the slasher and sizing rooms where they have big gangways and plenty of room for moving things round. They have, in the up-to-date mills, automatic conveyers, and make as much use as possible of gravity feed; that is to say, they start the raw material on the top floor and work downwards. The material is put into suitable boxes, it is carried along to the end of the room along rollers, and then shoots down a spiral shoot on to the next floor ready for the next process. For moving warps to the sizing room, I think I am correct in saying in every case they had overhead mono-rails for taking the materials away, and not trucks on the floor.

The next point is the lay-out of the machines in the rooms. Generally speaking, instead of having the rows of machinery down the length of the room, as we usually find in this country, they have them the other way, across, with shorter and rather less diameter shafts than we have; that is to say, when they use

overhead shafting at all. I should say in most cases the machines are individually driven, even the opening machinery and cards, and so on. Then they take very great care in the planning of their lighting systems. In nearly all cases they have the R.L.M. reflector. You can go into the rooms at night without experiencing any uncomfortable sensation due to glare. In one or two machine works or shops we observed the use of mercury-arc lamps. They gave a very good light, two or three feet long, and you can look at them without getting blinded, relatively speaking. Labour-saving devices are adopted practically everywhere. They endeavour to cut out human effort in all details. They avoid having a man whose job it is to do nothing else but push things about on the floor.

In one mill we saw a "Barber-Colman" bobbin winder and high-speed warper. The bobbin winder does all the piecing up. All the operative has to do is to bring along the spare bobbins and put them in the frame and the machine "does the rest" at a remarkably high speed. The high-speed warper runs at a speed of 500 yards per minute or little short of 20 miles an hour and makes an extraordinary good warp, a 31,000 yards of 29's complete, and, allowing for short stoppages, run in 80 minutes. Then we found there is a general use of weavers' knotters in order to save time. There is no hand knotting. There is no kissing of the shuttles. All shuttles have self-threading eyes, and cast-iron eyes are favoured more than the brass ones. There is an extensive use of compressed air for cleaning opening machinery, with nozzle-pressure of 40-60 lb. per square inch. Admittedly, they make a lot of dust in doing it but it does not settle back on the machines. They will go round with the compressed air nozzle for so long, and then sweep away the stuff on the floor. In that connection, there is a very interesting cleaning device used for ring frames; i.e., a blower—a small electric fan—travelling on a mono-rail over all the frames in one room. It consists of two arms down which air is propelled on either side of the frame. It simply moves along the frame blowing dust down. You might say that that stirs up a current of air and makes the dust fly, but it has the advantage that it does not allow the dust to collect, and you are not likely to have slubs and that kind of thing in the spinning, while the dust always collects on the floors.

I would like to mention one or two points concerning technical education. It is evident that America relies almost entirely on its technical development for keeping its place in competition, not only as between the North and South States, but with other countries. Consequently you find the mill men in America have a very much greater interest in the work of their technical schools. The specialisation of the operatives' job makes it such that they cannot draw on that class of people for their overlookers because they do not get sufficiently extended experience, consequenty they rely on the technical schools to turn out overlookers. They admittedly have to go through some sort of experience. They do not come straight from the school to take on the job. The mill superintendents and the executive class rise of course from the overlooker class. Also, the people who are determined to go straight into executive positions attend the technical schools very regularly. Technical education in textile matters is supported wholeheartedly. The Massachusetts Institute of Technology wanted to raise five million dollars for extensions to buildings, and they had four million dollars subscribed provided that they could raise another million dollars in six months. They did it in three months, and they got the five million dollars.

Another point might be worth mentioning; that is the overlookers there apparently take much greater care in the training of new operatives than one finds to be the case in this country; consequently the operations are carried out uniformly throughout the mill and not left entirely to the ingenuity of the operative himself.

Finally, the interchange of ideas is very free, and much freedom in allowing other men to come round their mills is permitted. That applies particularly in the South. Their attitude is this—You can get just as much out of the other man if he goes round your mill as he gets out of you, and it always helps you to

discuss your problems with him, and you learn more by going round seeing other people's mills than you do in any other way. At the end of the trip a man asked me if we had had any difficulty in getting round the mills. I assured him that we had not and that we were shown everything, and that in many cases we were told things which were distinctly in confidence but they trusted us. He said, "Mr. Morton, when you get back to your country you might tell your people that; because I tried to get round a lot of mills in your country and I did not succeed in a single case."

Mr. H. G. Greg said—I should like to sketch the methods of production in America, as far as the personnel and their domestic difficulties are concerned. It is perhaps particularly interesting to look at this problem to-day because in America there are two distinct sources of production. You have the Northern mills, the New England Mills round Boston, some of which have been in existence for upwards of 50 years, and the Southern mills which extend practically throughout the cotton-growing belt in Texas, Oklahoma, Georgia, and North and South Carolina. The Southern mills have certain advantages as far as labour is concerned. In most cases their hours of employment are not controlled by any State Laws, whereas in the North they have their own laws, which would roughly correspond to city and urban district council bye-laws in this country, as opposed to Federal Laws, or what we term "laws of the land." There are no Federal laws covering hours of labour in America in the textile industry. The North is now beginning to feel competition from the South where the conditions are rather easier as far as labour is concerned. They have been faced with the problem we are facing at present of the tailing-off of markets and of difficulty in securing business. In one or two cases we heard it mentioned that during the war the capacity of the country to produce textiles had increased out of all proportion to necessity; the capacity of the country to absorb the goods being now much reduced. These people are really out to get business, and they have said "The business is there if we can get it. If our competitors can get it we can get it, and it is up to the best man to get the business, and we are going to be the best men." I will take one particular instance of a mill which they told us would have closed down in a couple of months if it was run on the lines it was two or three years ago. They were literally desperate. Their method of tackling the situation was to get scientists to study their scheme of production. The scientists realised to begin with that the essential thing was to get the work to run well. They realised that there are certain operations such as creeling, doffing, and warp-changing that are discontinuous since each involves periodic replenishment of bobbins, beams, &c. They realised also that if they could stop end breakages their whole scheme would go through more smoothly. The first point they dealt with was the humidity. They proved conclusively, as it had been proved in this country, of course, that cotton spins best under certain conditions of moisture and certain conditions of moisture are more pleasant to work under. In their climate they cannot guarantee humidity at all, and they go in very extensively for humidification and pay great attention to it. In most cases it is done on systems like the "carrier" system, whereby they have all the windows shielded. They keep the workrooms under slightly greater pressure than atmospheric pressure, and they push "doctored" air in; "doctored" to the right temperature and humidity. The air works out through the windows and doors and liftways, and so on. Roughly, I think their figures are about 62% relative humidity for spinning and 82% relative humidity for weaving.

The next point they considered was how best to apportion their labour. I would like to take a spinning frame as an example, because from that we may get their idea which we can then apply to cards and other machinery. The most important thing is the actual piecing up of an end; the most difficult operation to perform. They, therefore, took the number of frames they had, after they had satisfied themselves the work was running well. They discovered how many breakages there were per day, and how long it took a particular individual to

piece up a particular end. They found out how many ends per diem an individual could piece up. They then worked out how many frames would give that individual just that number of ends to piece up. They realised it was a waste of time having that individual dusting, seeing to broken bands and tapes, and creeling, and that it was a less-skilled job which could be done by someone who was paid less wages. They found that all the subsidiary operations like creeling, oiling, and banding could be mapped out. Therefore, we get the extraordinary position of one spinner minding up to 24 ring frames, but we must realise that he or she only pieces up ends and does not do the whole operation.

Another way in which they have been able to economise is by grouping their mills together in big federations with a central clearing house for the receipt of orders, so that the various orders can go to the mills most fitted for their production. This enables individual mills to keep to very few counts of yarn and to plan out their production between their opening, cards, drawing frames, combs, down to ring frames and looms, so there was no bunching of roving in one place and no lack of intermediate bobbins in another place. In one intermediate frame the bobbins in a creel were dressed like a regiment of soldiers. At one end the bobbins were full, half way down part full, and at the other end empty. The creelers knew exactly at any minute of the day which particular frame they should be creeling and which particular frame would be next to creel. They were there with their barrels, and took the empty ones out and put full ones in. All frames had special doffers for the job—intermediate, jack frames, and spinning frames. All the organisation, of course, is based fundamentally on piece rates of wages. The spinner was paid on the production of the 25 frames minded, the doffers were based on the 20 or 30 frames they doffed, and creelers were on exactly the same basis. In every case where piece rates have been established the work has been split up so that the operative can produce more than before piece rates were established, and the operative has been given a very material benefit upon increased production. For instance, by the splitting up of labour one spinner, instead of minding two or three frames, doing creeling, piecing and everything, would turn out very much greater weight of yarn on 24 frames. She did not get the full advantage of the production of 24 frames as if she had creeled and cleaned them but she did get a very material advantage. This brings about a very curious point of view. When they start piece rates, first of all, they have to establish a basis of average earnings for a spinner. They then base the piece rate so that the spinners may get 10% or 20% more wages than on a day rate if they do a stated and reasonable amount of work. Whereas the day rate was 60s. a week, they are now earning 80s. a week. Any further piece rates will probably have to be based on the 80s. and they will probably get 120s. What will happen after two or three generations of that sort of thing having occurred I do not know, but that is one of their problems.

The present situation in America is interesting in most cases where automatic looms have been started, and where this entirely new method of splitting up work is concerned. There have been strikes, the workpeople saying that the mill owners are trying to get the better of them, and that the conditions meant starvation for them. A strike usually lasts from one month up to nine or ten months. In America if they have a strike they let it go on. They believe that after a time the strike will be over and the workpeople will come back on the owners' terms. But the mill managements are now going in more and more for the policy of educating their workpeople and of taking them into their confidence. They are finding it a tremendous advantage to do so. The managements are only too glad to have a quiet talk over the table in the evening with their workpeople while they all smoke their pipes. They explain their difficulties, how their production is too costly, and point out the mutual benefit of adopting a new system. The workpeople, nowadays, instead of being suspicious, appreciate the point of view of the management. They appreciate that the management are not altering the scheme of things purely for their own benefit, but that there

is a very material benefit also to the workpeople. They are giving the management their wholehearted support in consequence.

In the Northern States the workpeople are of many races, comprising practically every nationality. You can go into some mills and see notices posted up in from four to ten different languages. There is not the same solidarity of labour by any manner of means that there is in this country. If one mill goes on strike the mill next to it has not the least compunction in taking in their workpeople or doing all their trade. They look upon the situation in this way—"Well, these people are more stupid than we believe ourselves to be. We treat our workpeople well. They will stand by us. If they are unlucky, and cannot go on without a strike, and it is any benefit to us, we shall take the benefit."

Another point about the labour situation is the extraordinary fluidity of labour. If a man has been a cabinet maker, and he finds that from some cause or other cabinet making work is not available, he will turn his hand to something else. He may go for a short time to a technical school during the daytime, and he will keep himself by taking a night watchman's job or working an elevator during the night, which seems to be the stock job for anyone who gets the "sack." Then he goes to a mill. He will go through the hands of the overlooker, who will go to great pains to teach him the proper way to do things. If they can make him do things they will keep him; if they cannot then they have not the least compunction in dismissing him. Their method of determining a man to be what he claims to be is to see him at it. If there is a blockage through one operative being slow, they will go to considerable pains to investigate the case and to see if the work is right, if the frames are most convenient for the height of the worker, or if the light is wrong. Then if they are satisfied that they cannot increase the production of the operative through mechanical means they resort to dismissal. Owing to the relative scarcity of labour anyone who is "sacked" from one job can get another job without difficulty if they have really the will to work.

Another point to which they pay great attention is advertising. They like to produce what is most suitable to them, and they plan out their mills to produce it easily and very cheaply. They go to great pains in advertising their products in order to get buyers to say "The stuff you are making is just what I have been looking for."

It has already been mentioned that a mill likes to do all its blowing, spinning, dyeing, weaving, bleaching, and finishing under one roof. That enables the management to secure a balanced working and to retain the profits from the intermediate processes. It enables the spinner to appreciate the weavers' difficulties with their yarns, and the spinner is able to rectify any faults and make the weavers' work easier. The finisher gives advice to the spinner. The whole thing is very much quicker in its cycle. If you have the whole thing under one roof you can push the spinning and weaving through quickly and get on to the finishing, whereas if it is split up the finisher may have a lot of work in from somewhere else and there is a stoppage. They have recently adopted a system of "selling houses" by means of which they are enabled to get in direct touch with the customer, and thus enable the manufacturer practically to have his own finger on the market's pulse. That is almost as big a development as any that they are going in for.

The conditions in the South both in respect of results or methods of production differ greatly from those in the New England mills. There are no mill towns in the South. There are no "Stockports" or "Boltons" there. When people build a mill they also build a town for their operatives. Not only do they build the houses that the operatives live in but they build a school, a church, and very likely a technical college; there is nothing in the village except the mill and the operatives. The mill runs its own baseball team, its own cinema, and they rent their houses approximately at a rate of one shilling per week per room. Therefore, they have a pretty good control over their workpeople. The workpeople cannot move into another town or into another house because it is all

controlled by the management and there they have to stay. The management are complete despots but they are most philanthropic. In every case that we saw the mill villages were clean, the houses were in good condition, the operatives were happy and contented, and were being looked after by the management as well, and probably better, than they could have looked after themselves. In the mills the scheme of production is following fairly rapidly that of the New England mills; in fact there is a great tendency for the New England mill owners to build a mill in the South and overcome the difficulties of mixed labour that they have in the North. We were told that we would see negroes and children working in the Southern mills but that is a big mistake. A white man will not associate with a negro at all in the South, and the control of child labour, not by any Statutes, I think, but by mutual consent, is such that there are no young persons employed at all. Their production costs are considerably less in the South owing to the simpler life the operatives lead. They do not, of course, earn such high wages, because they have not increased their efficiency by piece rates and splitting up of production to the extent as the North has done, but they are a considerable source of competition to the North.

In conclusion, I wish to endorse what Professor Morton has said. The kind way in which we were received almost made us blush. You had practically only to turn up on a doorstep and they would greet you, invite you in and put you up for the night. The people there are always having conventions, and they go to great pains to attend them all, and they discuss their views with great freedom. As soon as a man has a new idea he goes and tells his neighbours about it at a convention, while he himself receives perhaps a dozen new ideas from other speakers, so that the exchange is a profitable one from his point of view.

Mr. John Crompton, in proposing a vote of thanks to the lecturers, said that what had been told them brought vividly to mind things that he himself saw in the States some years ago in company with Mr. Greg, Senr. There was ample food for thought in what had been told them. With regard to the exchanging of ideas at conventions which had been referred to, this was a system which the Textile Institute were really endeavouring to adopt by the holding of their luncheon-hour meetings. If there was a free interchange of opinions at such meetings then some of the objects for which the Institute was established would be achieved. It was very interesting to learn that their American friends went to the colleges for their foremen. It was quite correct to state that the trade unions in America were not so strongly established as those in Great Britain. It was necessary for both employers and trade unions to work together in harmony for mutual benefit, and then the workmen would receive the full measure of reward for their labour.

Mr. Fielden briefly seconded the vote of thanks, and it was carried by acclamation.

Yorkshire Section

Meeting held in the Council Chamber, Town Hall, Bradford, 7th October 1926, The Mayor of Bradford (Alderman Joseph Stringer) presiding.

ADDRESS ON SOME MODERN ASPECTS OF TRADE AND INDUSTRY

By the Rt. Hon. PHILIP SNOWDEN, P.C., M.P.

Having been introduced by the Chairman, Mr. Snowden said he proposed to speak on some of the wider aspects of trade and industry. He did not bring them a panacea, the immediate application of which would restore trade and ensure prosperity. It might be profitable, however, to consider the principles upon which rested industrial prosperity. There was a feature of the present industrial and economic situation which was perplexing students of the subject. There had been for some years a registered number of unemployed never below

1,000,000; wages had declined in the aggregate by £500,000,000 a year from the peak figure of 1920; the export trade was only three-quarters of the pre-war figure. Yet, in spite of this, the general standard of living was probably never higher, except during a brief period of the war. The amount of money spent in amusements and upon holidays was increasing; 30,000,000 people attended cinemas every week; there were over 2,000,000 homes with wireless installations. These expenditures were recent developments. The figures of savings banks, building societies, sales and membership of co-operative societies were expanding. The profits of retail stores were never higher than to-day. One firm manufacturing cheap motor cars was turning out a new car every two minutes of the working day. The country was being covered by a network of motor 'buses, and tens of millions of people were patronising that means of locomotion. The amount of expenditure on drink, though the amount of liquor consumed was less, was twice the 1914 figure. What was the explanation of the paradox? Unemployment was confined in the main to three or four of the great export trades. He did not think the unemployment figure was very greatly in excess of the actual number of unemployed at times of severe depression in pre-war days. The cost of living had fallen from the peak figure of 325 points to 74 points, and if they took industry as a whole they would find that the reduction in wages had approximated very closely to the reduction in the cost of living. That applied in particular to the two classes of unemployment known as sheltered industries and unskilled labour. What was the explanation of this obvious higher and better standard of living? It was to be found in the fact that in recent years there had been large grants from public sources towards certain social services. The working class was being helped in this way to the extent of £164,000,000 a year.

Proceeding, he said the huge sum of £308,000,000 per year was being paid in interest in War Debts, and this was, in fact, a transference of purchasing power. It was robbing Peter to pay Paul, but the fact remained that the Peters and the Pauls were to a very large extent the same people. There were two powerful and serious economic arguments against the interest on the War Debt. The first was that the interest on this debt went in the main to the people who would not spend it on the patronage of the staple industries of the country—it went mostly to the luxury trades. The other argument was that the War Debt lowered national credit, kept up the price of new capital, and was a detriment to trade and industry. Anything that could be done to increase the purchasing power of the people of this country was a direct encouragement and stimulus to trade.

Turning to the depression in the export trade, Mr. Snowden said that for the last eight years it had been a matter of constant surprise to him that, bad as our foreign trade had been, it had not been infinitely worse. The four main causes of the depression were—(1) the decreased purchasing power of the countries that were formerly the customers of the manufacturing nations; (2) the political instability which had followed the war; (3) the exchanges; and (4) the want of capital. Alluding to the return of the gold standard, he said he thought it was done too hastily, and this was not good for a country. The deflation was carried out too rapidly. These were some of the temporary and, he hoped, passing influences which were preventing the recovery of world trade. Dealing with what he described as influences of a more permanent character, Mr. Snowden said we could no longer hope or expect that Great Britain would have a monopoly of the world's trade. Other countries were becoming industrialists, and were dealing with the manufactures that needed no great amount of technical skill. Great Britain would have to rely very largely for its foreign trade on devoting energy and enterprise to the production of high-class goods. An examination of the table giving the exports per head from the United Kingdom to the countries of the world showed a striking disparity between the volume of goods purchased by these countries. It was the countries with a high standard of living which were our best customers. The fact that the British Colonies were our best customers was not alone due to the fact that they were our own kith and kin. Two other

reasons were that they had borrowed largely from the home country, and their exports were to a considerable extent the payment of interest on these loans; and that they had a high standard of living.

Mr. Snowden went on to point out the increase in the volume of world trade that would result from the raising of the standard of living in such countries as India, China, and Africa. In regard to India, he said that the exports were 5s. 3d. per head of the population. If the purchasing power of the nation were raised by a penny per week, India would take £60,000,000 more than she did at the present time. They must look to the countries where the standard of living was still low for the expansion of world trade. They were hardly yet at the beginning of the world trade; it was in its infancy. The development would be comparatively slow, but it could be done. One of the most serious barriers was the tariff. In the last few years, 25 countries had modified their tariff rates and in practically every instance the alteration had been an increase. This was due to the ineffectiveness of tariff barriers to protect the home industry, and to the idea that it was a good thing to make the country into an independent economic unit. The country with a tariff constantly needed to raise the amount of the tariff and that was itself conclusive evidence of its ineffectiveness to attain its object. Tariffs stimulated the competition of world-rivals. The desire to make the country an independent economic unit arose from a delusion. They did not realise that trade was an exchange of commodities. The same delusion was behind the slogan, "Buy British Goods." There was no country in the world where the uttering of a slogan like that was likely to be so disastrous to trade. A statement was made by the President of the Board of Trade recently that every time one bought a foreign article one deprived a British workman of a job.' No statement could be more foolish or more grotesque. Suppose the foreigner took up that position, where would the British export trade be ? He did not think the Governments of this country had done all they might have done in the way of bringing pressure to bear upon other countries to reduce their tariffs. He thought Government action ought to be taken to refuse to let London be an open market for the raising of capital for foreign countries unless some reciprocal advantage was given in the way of a reduction of tariffs. He thought much could be done through the League of Nations and the International Chamber of Commerce to bring about an international reduction of tariffs. The greatest of all the barriers to international intercourse was war. He believed there was going to be trade enough for everybody, but peace at home was vital and essential. "If we are going to have a succession of industrial disputes, there is little hope or prospect of the progress I believe it is possible to realise. The obligation to avoid industrial trouble is not imposed on one side or the other. It is an obligation on both sides. I hope there is a growing appreciation, both amongst workers and employers, for the maintenance of industrial peace, and this can only be done by doing justice all round. The employer must realise that there must be a progressive improvement in the standard of life of the workers, and that it is fatal to try and reduce costs by attacking wages. That is the worst policy that could be adopted.

In conclusion, Mr Snowden said the present coal dispute was due to the inefficient handling and use of coal. We could not have a satisfactory settlement of the coal problem unless we eliminated the waste involved in our present methods of dealing with coal. (Applause.)

On the motion of Mr. John Emsley, seconded by Ald. W. Turner, a hearty vote of thanks was accorded to Mr. Snowden.

Joint Meeting with the Batley and District Textile Society in the Batley Public Library, 30th September 1926: Mr. T. C. Taylor, J.P., being in the chair.

Opening the proceedings, Mr. Taylor said that upon the head of a woollen manufacturer's business rested the responsibility of seeing that a very great variety of processes were competently managed. In their trade, at least, there

was never a piece of cloth which had not to pass through the hands of at least twenty different persons before it got to the merchant. He could not imagine any business in which the team spirit was so necessary as in theirs. The securing of competent managers and foremen for such a variety of departments was itself no easy matter for the head of the concern, and the two qualities necessary in every manager were personal fitness to manage men and technical knowledge. Some men possessed the first of these qualities and others the second, but very few possessed both. While not everyone agreed with him, continued Mr. Taylor, that the profit receivers should share their profits with the workers, there were many firms who took a real interest in their workers, and if they did so the workers knew it. Only if the employer did his best for his workpeople, could he expect them to do their best for him. Employers must make those under them see that it was in their interest to do their duty, and should try to make it their pleasure too. They must employ the heads and hearts of their workers as well as the hands. Recent observers from this country of industrial relationships in the United States appeared to agree on the absence of "ca-canny" in American industry. Employer and employed appeared to co-operate in securing the largest possible amount of production. Real wages were high and there was an absence of "that ignorant and mischievous doctrine that we can get more by producing less." He then asked Mr. G. Garnett, a Vice-President of the Textile Institute, to deliver his address.

After thanking the Yorkshire Section of the Institute for the invitation to speak before this meeting, Mr. Garnett said that in his opinion, and in the opinion of others, we have rested too long on our laurels, and that apart from economic factors, which are more or less international in their effect and, therefore, less controllable by ourselves, other nations were successfully competing with us in securing a much greater proportion of the world's markets than formerly. He therefore proposed for a short while to attempt a brief survey of what was being done at home to meet these external competitive conditions. He first wished to deal with advances in the scientific investigation of industrial problems from, of course, the aspect of the wool textile industry. The underlying principles of technical processes were to a considerable extent known and understood by our forefathers, and a measure of the success they achieved is to be found in the number of people normally employed in the industry, namely, 300,000. Natural facilities, as well as inherent aptitude, had helped them to be first in the field, and though to a great extent these advantages are still our inheritance, they are not in themselves sufficient to keep us in the premier position. In 1918, under the guidance of the Department of Scientific and Industrial Research, the British Research Association for the Woollen and Worsted Industries was formed to deal with pure research, with investigation of specific problems, and to give technical and scientific assistance to members of the Association. Such work had been needed for some time, but it was only by the formation of an association of firms that it was possible to meet the cost. He had no hesitation in saying that the Association had justified its creation and had only to refer to such investigations as "Electricity in Wool," "Causes of Colour Fading," "Standards of Regain," and "Migration of Alkali in Damp Scoured Cloth," to illustrate the important character of the work done and of the information given to subscribing firms. On the mechanical side, the Stroboscope had revealed the irregular speed of spindles, a contributory cause of yarn imperfections, and thrown thereby much light on the causes of faults previously unknown. He felt, too, that of particular interest to the Batley district, would be the experimental carding set now running at Leeds on various types of blends. From this set, mechanical improvements which should have far-reaching results were confidently expected. All this, said Mr. Garnett, involves much work, time, and patience, and could only be continued if it had the whole-hearted support of the trade. The income of the Association would have to be considerably increased in order to comply with the conditions upon which the Government grant was now being given.

To let the work of the Association diminish or die of starvation would be sheer madness, and would be equivalent to leaving the field to our competitors.

Mr. Garnett, proceeding, said that he was confident that an *esprit de corps* was now definitely discernible in industrial life. It was eminently desirable that those engaged in industry should be imbued with a sense of fair play, should recognise the rights and privileges of others, and should believe firmly in joint action for the common weal. Such a spirit he felt now definitely animated industrial life and found practical expression in the welfare schemes with which all would be familiar. The establishment of dining rooms, sports grounds, savings clubs, and pension schemes, all served to prove that those in control of our big industries realised the value of anything that might bring into closer contact all sections of masters and men. Such movements as those of the boy scouts and girl guides played their part both in industrial and in civil life in helping those concerned to realise the value of team work. Not only did these considerations make for greater personal efficiency and better quality of work, but they resulted in a fuller knowledge of others, coupled with a sense of inter-dependence and a recognition of the value of co-operation. Speaking of the development of trade unionism in industry, Mr. Garnett said that though the trade union must be recognised as an integral part of the constitution of industry, he was afraid that trade unionism had developed upon lines destructive rather than constructive. It cherished prejudices directly contrary to that spirit of fair play and mutual confidence for which he was pleading. Both Capital and Labour appeared to wish to divert attention from their own faults by over-emphasising the faults of the other side, and it was not until both sides would look their own faults plainly in the face that industry would be relieved of the dead weight of mutual suspicion and mistrust. He referred to the different state of affairs in the United States, but said that he hoped in this country we should go further—as was, he thought, our habit—and achieve a wider perfection.

The grant of a Royal Charter of Incorporation to the Textile Institute, said Mr. Garnett, may be said to have marked the beginning of a new era in textile technological qualification. Under the Charter, a diploma scheme was in course of establishment and members of the Institute whose qualifications were accepted as satisfying the requirements of the Institute's bye-laws might receive Diplomas of Associateship or Fellowship of the Textile Institute. In brief, this meant the creation of a new post-graduate qualification and distinction. This should prove a powerful incentive to young men in the industry to continue their training and not to mark time in relation to textile technology during their early years in the textile industry. He was pleased to say that Mr. J. H. Lester, Chairman of the Selection (Diplomas) Committee of the Institute, was present, and would deal at greater length with the scheme. In conclusion, he wished to re-emphasise that in his belief the lines of development along which the industry should make every effort to progress were those of scientific research, of closer co-operation and mutual goodwill between all concerned, and of higher technological qualification.

Mr. Lester, being called upon to address the meeting, described in detail the methods by which the diplomas of the Textile Institute could be obtained and paid a tribute to the work of Mr. John Emsley in obtaining the Royal Charter for the Institute. The textile technologist, he said, was someone acquainted not only with the science but with the art of textile manufacture. It was a case of the combination of theory and practice, and they did not say the one or the other was supreme. The industry in the past had been built up, not on science, but on art, on rule-of-thumb, on the cleverness of their forefathers. They would be unwise to abandon that heritage and to submit to the dominance of science. Describing the "royal road" to Associateship of the Institute by way of the universities, Mr. Lester said that unfortunately few of their students could enter the door to the university even after passing the matriculation examination. Though they might obtain a County Council grant which would provide for their

fees, they had not always the means of obtaining the necessary money for their maintenance. It was, he thought, a disgrace to the country that so small a proportion of the poorer members of the community could possibly obtain scholarship and maintenance grants to enable them to go forward to the universities. He felt that the textile industry to-day was not in a healthy condition and he was not inclined to be optimistic for the future. The student of to-day by no means utilised, as he might, the facilities that were provided for him and that enabled him to lift himself above the common level. Moreover, with many notable exceptions, it must be admitted that as regards the directorate and management of by far the larger part of the mills, the training which the heads of the concerns had received was not such as they should really have had.

Mr. John Emsley, referring to his own work for the Textile Institute, said that any man who had benefited by his industry ought to put something back into the industry. It had been a privilege to him to have been able to take part in the securing of the Charter. Unlike Mr. Lester, he was rather optimistic. We had had what was really a revolution in this country; we had had to decide whether we should be ruled by order or by mob law, but when we got over these troubles there was a great future for this country. The spirit between man and man would be better, and both employers and employed would benefit.

The interesting discussion which followed was terminated by a vote of thanks to the speakers, proposed by Mr. C. Varley and seconded by Mr. N. B. Radcliffe.

South of Scotland Section

Meeting at the Technical College, Galashiels, on Thursday, 30th September 1926.

ARTIFICIAL SILKS—PREPARATION AND PROPERTIES

At this meeting, Mr. Ninian Kemp occupied the chair, and there was an excellent attendance, considerable interest being evinced in the special display of yarns and fabrics which had been secured by the Institute. Exhibits had been kindly lent by Mesrs. Courtaulds, Ltd., and the Celanese Company, whilst a general collection was forwarded by Mr. P. E. King, of the Department of Dyeing, Leeds University. Exhibits of fabrics showing cross-dyeing effects were supplied by the Research Department of the Bleachers' Association. The interest in the display was so marked that the collection was allowed to remain available for inspection for a few days.

The Chairman, introducing the lecturer, Dr. J. C. Withers, of the British Cotton Industry Research Association, said he was sure everyone there would be anxious to hear what Dr. Withers had to say in regard to this important development in the textile industry. He than asked Dr. Withers to address the meeting.

The Lecturer explained that whilst most of the many valuable papers which had been read before audiences of textile workers during the past few years dealt exclusively with dyeing or emphasised the merits of the products of a particular firm, he would attempt to give a review of the whole field and discuss such ascertained properties of the various artificial silks as were important in their application or would serve to distinguish one from another. After a short historical introduction, he gave an outline of the processes underlying the manufacture of the four main types, namely, Chardonnet, cuprammonium, viscose, and cellulose acetate silks, pointing out those stages which require careful control and which profoundly affect the quality of the final product. He explained that the first three types are really cellulose, differing considerably in physical properties, but only slightly in chemical properties, from cellulose as found in well-scoured cotton, whereas cellulose acetate silk is chemically quite distinct, being a compound.

Dr. Withers then explained the denier system of counts and gave examples of the wide range in the number and dimensions of single filaments in threads

of about the same counts, showing that the appearance and feel of real silk are more nearly approached by threads composed of very many slender filaments. He then reviewed what was known of the microscopic appearance, tensile, optical, and other properties, quoting largely from the published researches of the Forschungs Institut für die Textilindustrie, Dresden. It was explained that certain measurements made on cross-sections can be used as a distinguishing test between artificial silks, whilst the actual outlines of the sections often afford a clue to the nature of the spinning baths used in their manufacture. More simple chemical and physical tests were summarised. Moisture regain and the serious effect of moisture on the tensile properties of artificial silk were also discussed.

Difficulties in sizing, winding, and weaving were briefly mentioned, and it was explained that defects due to variable tension are magnified enormously with such lustrous materials. Actual examples of lustre faults in fabrics were exhibited, and the use of photography and the microscope in examining them was described. Finally, brief references were made to the dye affinities of the various types.

On the motion of Mr. R. S. Hayward, Dr. Withers was heartily thanked for his services.

The General Secretary of the Institute contributed a short statement in reference to the Institute's Diploma scheme, and moved a vote of thanks to the Chairman, which was carried by acclamation.

CONFERENCE OF REPRESENTATIVES OF TEXTILE SOCIETIES AND KINDRED ORGANISATIONS

Visit to Blackburn Technical College

A conference of representatives of Textile Societies and Kindred Organisations of Lancashire, Yorkshire, and the Midlands, took place at Blackburn Technical College on the afternoon of Saturday, 9th October. Over fifty delegates were present and were welcomed by Mr. J. W. Marsden, J.P., Chairman of Blackburn Higher Education Committee, by Mr. Charles Tate, President of Blackburn Textile Society, and by Mr. J. H. Dawson, President of Federation of Textile Works Managers' Associations.

Introducing the discussion on "The Work of Textile Societies and its relation to Technical Education generally," Mr. J. H. Dawson, of Brierfield, said that the public spirited organisations represented at that conference exerted a wonderful influence on technical education in regard to the textile industries. The whole atmosphere of textile societies was one of technical education. There were 33 societies represented and the total membership was over 10,000, which certainly indicated the potentialities of the movement. Some of the societies had prepared the soil for to-day's technical education, starting as mutual improvement societies, and leading up to the mechanics' institutions, long before municipalities and Governments thought about the importance of the subject. The ideal remained with these societies and, in nearly every case, their first aim and object was "to further the interests of the textile industry by educational and other means." There was still great opportunity for the societies, and the unselfish character of their work was probably not fully realised by themselves. He believed it was still possible for these organisations to mould the tendencies of technical education of the future. Their endeavour was in the direction of making occupation intelligent and interesting without drift into drudgery. This was what some of the old Textile Craft Guilds engaged in, and he thought some endeavour might be made to resuscitate the spirit of those Guilds and apply it to modern industrialism. A good many young men in the industry were liable, apparently, to reach the state commonly described as "fed-up," whilst at the other end of the scale there were individuals who erroneously considered

their knowledge all-sufficient. If textile societies could remove either of these defects, the achievement would be great. As a matter of fact, the real benefit and interest of technical education only accrued subsequent to class or course instruction. The textile societies provided for continuance of technical education, and since the Textile Institute had set up its post-graduate qualifications, the whole movement was carried forward and achievement in continued technical education could be properly recognised.

Mr. W. Wilkinson (Head of the College) said the textile societies afforded a very necessary meeting ground for those who had received technical training. It was perfectly true that the student who completed the usual courses of training was not even then fully trained. The textile societies, and after that the Textile Institute, provided the avenue of progress.

Mr. W. P. Crankshaw (Bolton) expressed the view that it was not the business of the College to teach a man his job, this being the function of the industry.

The delegates spent a couple of hours inspecting the various departments of the College and their equipment, and on the motion of Mr. Henry Binns (Bradford), seconded by Mr. J. Chamberlain (Leicester), a hearty vote of thanks was accorded to the officials of the College, the Blackburn Textile Society, and the Federation of Works Managers' Associations.

It was decided that the next annual conference should take place in October 1927, and representatives were asked to give their organisations opportunity to offer an invitation to the conference as Blackburn had done on this occasion. Any such invitation should be forwarded to the General Secretary of the Textile Institute, Mr. J. D. Athey.

Some discussion took place regarding framing of syllabuses of lectures, and several representatives alluded to difficulty experienced in securing contributors. Mr. G. S. Leeson (Bradford) urged formation of "Syllabus Committees" definitely responsible for securing the programmes of lectures. The Secretary (Mr. Athey) pleaded for more frequent requests to members of societies to prepare papers, and interchange of services in this connection. Messrs. N. Collinson (Batley), J. Burgess (Ashton), and C. Barnshaw (Blackburn), also took part in discussion, and the proceedings ended with a hearty vote of thanks to the Chairman.

CIVIC WEEK CELEBRATIONS IN MANCHESTER

Manchester engaged in Civic Week celebrations—from 2nd to 9th October—when various institutions contributed in a variety of ways to the programme. In response to request, the Council of the Textile Institute agreed to arrange for a contribution by wireless in reference to the city and the cotton textile industry. Accordingly, on the evening of the 7th October, the President of the Institute, William Howarth, Esq., J.P., broadcast the following statement from the B.B.C. Station—

MANCHESTER AND THE COTTON INDUSTRY

Manchester is the centre of the British cotton manufacturing industry—the largest in the world and, in relation to our export trade, the most important of all British manufacturing industries. The complex commercial activities of this vast industry, and the warehousing, packing, and distribution arrangements are all concentrated here. Raw cotton is brought overseas direct to Manchester via the Ship Canal, and the fabrics manufactured therefrom are shipped to all parts of the world. Lancashire's consignments of fabrics stream out so that the location of the consumer may range from the proverbial "China to Peru." Native races in many climes are abundantly familiar with textiles from Manchester, but they know them by descriptions not commonly known throughout England (Dhooties, Sarongs, &c.). In exceptional cases, goods which are not usually seen in this country except in the process of manufacture, are sent regularly to a particular country where they are traditionally regarded

by the natives as of exclusive character, and the demand for them would be imperilled if the exclusiveness were seriously doubted. Manchester is undoubtedly the leading textile market of the world.

The organisation of the industry may be divided into three main sections—Manufacturing (which comprises spinning and weaving); Finishing (which includes bleaching, dyeing, and printing); and Marketing (at home and abroad). Spinning is mainly concentrated in South Lancashire and adjoining parts of Cheshire and Yorkshire, the fine spinning being centred in the Bolton and Manchester districts, and the spinning of the coarser yarns in Oldham, Rochdale, Wigan, and Stockport areas. The weaving centres are largely in North and East Lancashire—Blackburn, Burnley, and Preston being important districts. Finishing is to some extent a specialised industry in Lancashire, but is also usually combined with the bleaching, dyeing, and calico-printing industries. Enormous progress has been made and continues to be made on the finishing side of the industry, and it is on this side that the greatest advance has been achieved in recent years.

With regard to marketing, although some merchanting houses ship all kinds of cloth to all markets, the majority specialise on one particular market or group of markets. Thus, a business house is said to be in the Far East trade, the India trade, the South American trade, or it might be in the West African trade.

"Cotton wool" was at one time the common description of our raw material, and it was then regarded as a substitute for wool, much in the same way that so-called artificial silk has been regarded as a substitute for natural silk. Our cotton textile industry dates back to the latter half of the sixteenth century. It was not, however, until the middle of the seventeenth century, long after the introduction of the spinning of "cotton wool," that goods entirely of cotton were manufactured here. Importation of cotton goods from India was opposed by the old and strongly-entrenched industries of wool production and manufacture. Tariffs were set up in order to check the importation, but high tariffs and prohibitions appear to have given a stimulus to importation of the raw cotton and to home manufacture. It was mainly the successful spinning of cotton and the development of new and improved methods which enabled formidable headway to be made.

In the modern sense, however, cotton spinning and manufacturing is a comparatively new industry, commencing in the last twenty years of the eighteenth century. At the beginning of the nineteenth century our annual consumption of the raw material was equal to one hundred thousand bales, each of 500 lb. or nearly a quarter of a ton in weight. Large as the figure may sound, yet this quantity would not nowadays keep Lancashire mills running for a fortnight. By 1843, for the first time, the million bales mark was reached. The figure to-day of cotton consumed in this country—from all sources—is placed at well over three million bales per annum, which represents a consumption of over sixty thousand bales a week.

As in the early days achievement in spinning greatly promoted rapid development, so to-day the strength of our position in the world's competitive markets is greatly dependent upon the maintenance of supremacy in this section and of the high efficiency in the manufacture of fine cotton goods. The fact that approximately four-fifths of the world's mule spindles—the best instrument for the production of super yarns—are to be found in Lancashire, is a sufficient indication of the situation with regard to the production of fine cotton goods. Approximately, a quarter of the British cotton spinning industry depends upon Egypt for its supply of raw cotton of long staple. America still supplies the great bulk of the cotton required, but supplies of Empire-grown cotton are now regularly on the market, and increasing efforts are being directed to developments in this direction. Long-stapled cotton is essential for the fine counts of yarn in the spinning of which Lancashire stands pre-eminent. As the industry continues to develop in foreign countries, it is regarded as quite certain that

competition in the world's markets will become keener and keener, and will take a wider and higher range, with the result that Lancashire trade must tend towards a still greater proportion of fine spinning and the manufacture of cloths from yarns of fine count. The hope is that with world-wide advances in the standard of living the demand for finer goods will correspondingly increase. The adaptability of the industry to change of conditions inspires confidence as to its future—an adaptability proved, for instance, by the rapidity with which it has utilised artificial silk, and by the manner in which some districts have effected changes in the character of their productions in order to overcome difficulties of dislocation of trade and markets following the great war.

There are over half-a-million of insured persons in our manufacturing industry. The spindles number approximately 59 millions, or one-third of the world's total, whilst looms number 800 thousands. Normally, about 80% of the cotton fabrics produced are for shipment. Last year (1925) the exports of yarn exceeded 189 million pounds in weight. Of cotton cloth over 4½ thousand-million square yards were exported—an amount which, if converted into a continuous web, would provided a cotton bandage 100 yards in width right round the world. The figure of 4½ thousand-million square yards for 1925 compares unfavourably with 1913, when it was 7 thousand-millions, and it emphasises the severity of the trade depression of last year.

In addition to the manufacturing industry, the development of the British textile machinery industry has been remarkable. Just as Britain is the largest producer of textiles, so she is the largest manufacturer of textile machinery. It has been an enormous advantage to the industry that the engineering establishments have been developed in proximity to the mills, thus admitting of effective co-operation between machine maker and user. The annual export of textile machinery from Lancashire provides a substantial quota to the total value of the exports of this country.

Organisation as to trade and commerce of the industry has reached a high pitch of efficiency. The general organisation, however, is remarkable for the extent of its ramifications and the energy with which the various interests are pursued. The comparative freedom from industrial disputes, particularly in the very difficult post-war period, is high testimony to efficiency of control on the sides of both employer and employed.

Technical education has progressed rapidly. The modern movement of especial interest in this connection has been that of continued instruction long after entry into the industry. Indeed, the organisation to-day offers facilities for the maintenance of absolutely continuous interest in the technical problems of the industry. An indication of the progressive spirit which pervades the rank and file of the cotton industry is to be found in the number of textile societies, managers' associations, and other organisations, one or more of which exist in every important locality and which have for their object the promotion of a wider knowledge of the particular branch of the industry in which members are employed. These organisations, which have no real parallel in any other of our great industries, in addition to preserving existing technical skill, play a great part in the rapid dissemination of new knowledge.

The scientist and the technologist are being more and more employed. Moreover, the industry supports the largest of the co-operative research associations in the country—at the Shirley Institute, Didsbury. Many private concerns, too, maintain individual research departments. The Textile Institute, of which I am the President at the present time, and the headquarters of which are at Manchester, seeks to bring together to one common platform the technological and the scientific interests of the whole of the textile industry. This Institute promotes meetings and conferences for the reading of papers of technical and scientific interest, and also issues a journal which is regarded as the leading scientific periodical devoted to textiles.

Recently reconstituted by Royal Charter, the Textile Institute now provides for the award of post-graduate Diplomas, in the form of Associateships and Fellowships, to those of its members who qualify therefor by existing qualifications, or by examinations, or by both means.

Finally, it may be said for the cotton industry, that its gigantic output, its stupendous capital, and its strength of position in international trade, all combine to place it in the first rank of British manufacturing industries.

NOTES AND NOTICES

The Textile Society Movement

In the interests of technical advancement, the potentialities of the movement which has resulted in the establishment of textile societies and kindred organisations in the various areas of the textile industry are obviously great, when the numerical strength of the organisations is fully revealed, as was the case at the conference of representatives of these organisations which took place at Blackburn Technical College on Saturday, 9th October. A few years ago the Textile Institute, appreciating the efforts of the Societies, initiated a movement for the bringing together of the various organisations with a view to co-operation and discussion for mutual benefit. It may certainly be said that the movement has grown and an annual conference is now an established event. The Institute continues direct association with the movement, undertaking the secretarial work of the conferences, and bearing the incidental expenses. At the conference at Blackburn, Mr. J. H. Dawson, of Brierfield, President of the Federation of Textile Works Managers' Associations, opened a discussion on "The Work of Textile Societies and its Relation to Technical Education." It was characteristic of Mr. Dawson, as his utterance indicated, that he should have spared neither time nor effort to secure reliable information. By direct communication with the officials of all the organisations he had obtained first hand knowledge of their activities, objects, and numerical strengths. It was surprising to learn that the organisations represented at the conference had a total membership of 10,000, all of whom might be said to be interested in the technical advancement of the industry. The movement is probably on a scale without parallel in industry. The 1927 conference is to take place in October next and the General Secretary of the Institute would be pleased to receive, on behalf of the movement, any invitation on the part of a participating organisation, or from any textile teaching institution which might be visited in conjunction with the conference.

London Section Activities

The London Section, which started to arrange its winter programme somewhat later than usual, has already obtained the promise of several interesting papers. Among these must be mentioned "Development of Bast and Leaf Fibre Cultivation in the British Empire," by Dr. Goulding, of the Imperial Institute; "Fabric Testing for Retail Distribution," by Mr. W. C. Whittaker, who for many years has controlled the testing department of one of the largest west-end stores; "Flax Markets," by Mr. E. Wigglesworth; "Standard Lancashire Cloths," by Mr. A. R. Down; "Household Linen," by Mr. D. Anthony-Langsdale; and a paper on weaving faults, by Mr. L. J. Mills. Other functions which it is proposed shall take place are a visit to the Imperial Institute for the purpose of viewing the textile exhibits, a visit to a rope-walk, and a dinner-dance on the evening of the day of the Annual London Section Meeting. In all probability at least two of the papers will be read in the Clothworkers' Hall, by kind permission of the Clothworkers' Company. The courteous attitude of this great Livery Company, which for the past three years has generously placed its magnificent hall at the service of the London Section for certain lectures, provides a small but not unimportant illustration of the consistent present-day benevolence of the Clothworkers' Company to the industry of which at one time it was the governing body and guardian.

Section Meeting at Belfast

With a view to resuscitation of sectional activity in the area of which Belfast is the centre, a meeting of members of the Institute took place at the Technical College, Belfast, on the 16th September. Mr. W. H. Webb, of Randalstown, was voted to the chair, and there were also present Messrs. F. Anderson, F. J. W. Shannon, G. R. Beatty, R. V. Eves, W. H. Gibson, F. Bradbury, O. V. Greeves, J. Kirkwood, W. J. Cowden, and others. The General Secretary (Mr. Athey) attended and stated that it was the desire of the Council that a small Committee to engage in Section activities should be appointed. It was suggested that at least two meetings for the delivery of papers, with discussions to follow, should be arranged for the oncoming session, whilst members of the Section might possibly hold a meeting of a social character with a view to bringing members together. The Secretary also offered a statement with regard to the Institute's Diplomas, and explained at length the scheme of post-graduate qualifications to members and the conditions attached thereto. On the motion of Mr. Anderson, seconded by Dr. Gibson, it was decided that a Section Committee be appointed, together with an Hon. Secretary, in order to promote meetings. It was decided that the Committee be constituted as follows—Messrs. W. H. Webb, Dr. Gibson, F. Anderson, F. Bradbury, Jas. Crawford, F. J. W. Shannon, W. J. Cowden, G. R. Beatty, and J. Kirkwood. Mr. F. J. W. Shannon was unanimously elected Hon. Secretary, and the meeting was concluded with a vote of thanks to the Chairman and to the Institute Secretary.

The Textile Institute Annual Conference

Our report of the proceedings of the above-named Conference—held at Buxton (Derbyshire), 20th to 22nd October—will appear in the next issue of the Journal. The event has been postponed from last Whit-week owing to the general strike, which immediately preceded that week. Deferred events usually suffer, and if the attendance at Buxton was not quite up to the average, nevertheless it was indeed fortunate that the programme of lectures was available substantially in the form in which it was originally framed, Sir William Bragg kindly renewing his engagement to deliver the Annual Mather Lecture of the Institute.

Diplomas of the Textile Institute

Applications for the Associateship of the Institute have already necessitated the conduct of two oral examinations in General Textile Technology, the Selection Committee having insisted upon a satisfactory level of knowledge covering the whole field of textile technology in addition to attainment in a particular branch or in special branches. The Committee's experience of the examinations held suggests that the stipulation in regard to a satisfactory knowledge of general textile technology has not only been justified, but that it will need to be rigorously maintained. Indeed, the Selection Committee has recently considered the matter of the preparation of regulations and a syllabus to be issued in relation to future examinations of this character, and a special Sub-committee has been appointed to canvass the whole question, prepare a scheme, and report in due course to the Committee.

Research Directorship Change

The resignation has recently taken effect of Mr. H. J. W. Bliss, Director of Research for the British Research Association for the Woollen and Worsted Industries, the activities in connection with which are centred at Headingley, Leeds. Mr. Bliss had been for several years past in close and direct touch with the affairs of the Textile Institute, and his services were greatly appreciated. An announcement issued by the Association in question, states that following repeated misfortunes which have befallen the family of Mr. H. J. W. Bliss, M.A., F.I.C., he has asked the Association to receive his resignation, as he feels that a break with painful local surroundings would be in the best interests not

Recently reconstituted by Royal Charter, the Textile Institute now provides for the award of post-graduate Diplomas, in the form of Associateships and Fellowships, to those of its members who qualify therefor by existing qualifications, or by examinations, or by both means.

Finally, it may be said for the cotton industry, that its gigantic output, its stupendous capital, and its strength of position in international trade, all combine to place it in the first rank of British manufacturing industries.

NOTES AND NOTICES

The Textile Society Movement

In the interests of technical advancement, the potentialities of the movement which has resulted in the establishment of textile societies and kindred organisations in the various areas of the textile industry are obviously great, when the numerical strength of the organisations is fully revealed, as was the case at the conference of representatives of these organisations which took place at Blackburn Technical College on Saturday, 9th October. A few years ago the Textile Institute, appreciating the efforts of the Societies, initiated a movement for the bringing together of the various organisations with a view to co-operation and discussion for mutual benefit. It may certainly be said that the movement has grown and an annual conference is now an established event. The Institute continues direct association with the movement, undertaking the secretarial work of the conferences, and bearing the incidental expenses. At the conference at Blackburn, Mr. J. H. Dawson, of Brierfield, President of the Federation of Textile Works Managers' Associations, opened a discussion on "The Work of Textile Societies and its Relation to Technical Education." It was characteristic of Mr. Dawson, as his utterance indicated, that he should have spared neither time nor effort to secure reliable information. By direct communication with the officials of all the organisations he had obtained first hand knowledge of their activities, objects, and numerical strengths. It was surprising to learn that the organisations represented at the conference had a total membership of 10,000, all of whom might be said to be interested in the technical advancement of the industry. The movement is probably on a scale without parallel in industry. The 1927 conference is to take place in October next and the General Secretary of the Institute would be pleased to receive, on behalf of the movement, any invitation on the part of a participating organisation, or from any textile teaching institution which might be visited in conjunction with the conference.

London Section Activities

The London Section, which started to arrange its winter programme somewhat later than usual, has already obtained the promise of several interesting papers. Among these must be mentioned "Development of Bast and Leaf Fibre Cultivation in the British Empire," by Dr. Goulding, of the Imperial Institute; "Fabric Testing for Retail Distribution," by Mr. W. C. Whittaker, who for many years has controlled the testing department of one of the largest west-end stores; "Flax Markets," by Mr. E. Wigglesworth; "Standard Lancashire Cloths," by Mr. A. R. Down; "Household Linen," by Mr. D. Anthony-Langsdale; and a paper on weaving faults, by Mr. L. J. Mills. Other functions which it is proposed shall take place are a visit to the Imperial Institute for the purpose of viewing the textile exhibits, a visit to a rope-walk, and a dinner-dance on the evening of the day of the Annual London Section Meeting. In all probability at least two of the papers will be read in the Clothworkers' Hall, by kind permission of the Clothworkers' Company. The courteous attitude of this great Livery Company, which for the past three years has generously placed its magnificent hall at the service of the London Section for certain lectures, provides a small but not unimportant illustration of the consistent present-day benevolence of the Clothworkers' Company to the industry of which at one time it was the governing body and guardian.

Section Meeting at Belfast

With a view to resuscitation of sectional activity in the area of which Belfast is the centre, a meeting of members of the Institute took place at the Technical College, Belfast, on the 16th September. Mr. W. H. Webb, of Randalstown, was voted to the chair, and there were also present Messrs. F. Anderson, F. J. W. Shannon, G. R. Beatty, R. V. Eves, W. H. Gibson, F. Bradbury, O. V. Greeves, J. Kirkwood, W. J. Cowden, and others. The General Secretary (Mr. Athey) attended and stated that it was the desire of the Council that a small Committee to engage in Section activities should be appointed. It was suggested that at least two meetings for the delivery of papers, with discussions to follow, should be arranged for the oncoming session, whilst members of the Section might possibly hold a meeting of a social character with a view to bringing members together. The Secretary also offered a statement with regard to the Institute's Diplomas, and explained at length the scheme of post-graduate qualifications to members and the conditions attached thereto. On the motion of Mr. Anderson, seconded by Dr. Gibson, it was decided that a Section Committee be appointed, together with an Hon. Secretary, in order to promote meetings. It was decided that the Committee be constituted as follows—Messrs. W. H. Webb, Dr. Gibson, F. Anderson, F. Bradbury, Jas. Crawford, F. J. W. Shannon, W. J. Cowden, G. R. Beatty, and J. Kirkwood. Mr. F. J. W. Shannon was unanimously elected Hon. Secretary, and the meeting was concluded with a vote of thanks to the Chairman and to the Institute Secretary.

The Textile Institute Annual Conference

Our report of the proceedings of the above-named Conference—held at Buxton (Derbyshire), 20th to 22nd October—will appear in the next issue of the Journal. The event has been postponed from last Whit-week owing to the general strike, which immediately preceded that week. Deferred events usually suffer, and if the attendance at Buxton was not quite up to the average, nevertheless it was indeed fortunate that the programme of lectures was available substantially in the form in which it was originally framed, Sir William Bragg kindly renewing his engagement to deliver the Annual Mather Lecture of the Institute.

Diplomas of the Textile Institute

Applications for the Associateship of the Institute have already necessitated the conduct of two oral examinations in General Textile Technology, the Selection Committee having insisted upon a satisfactory level of knowledge covering the whole field of textile technology in addition to attainment in a particular branch or in special branches. The Committee's experience of the examinations held suggests that the stipulation in regard to a satisfactory knowledge of general textile technology has not only been justified, but that it will need to be rigorously maintained. Indeed, the Selection Committee has recently considered the matter of the preparation of regulations and a syllabus to be issued in relation to future examinations of this character, and a special Sub-committee has been appointed to canvass the whole question, prepare a scheme, and report in due course to the Committee.

Research Directorship Change

The resignation has recently taken effect of Mr. H. J. W. Bliss, Director of Research for the British Research Association for the Woollen and Worsted Industries, the activities in connection with which are centred at Headingley, Leeds. Mr. Bliss had been for several years past in close and direct touch with the affairs of the Textile Institute, and his services were greatly appreciated. An announcement issued by the Association in question, states that following repeated misfortunes which have befallen the family of Mr. H. J. W. Bliss, M.A., F.I.C., he has asked the Association to receive his resignation, as he feels that a break with painful local surroundings would be in the best interests not

only of himself, but also of the organisation of which he had been Director of Research since its inception. These circumstances are well known to many in the West Riding. The Research Control Committee greatly regret that under the circumstances they find themselves with no alternative but to accept Mr. Bliss' resignation. They are anxious that it should be understood that they hope and expect Mr. Bliss will obtain an appointment of a suitable character elsewhere, and they will give him all the assistance in their power. Sir James P. Hinchliffe and Mr. Henry S. Clough referred at some length to the spade work which had been done under Mr. Bliss' direction and to the fact that the Association has now become an effective force in the trade. Mr. Bliss expressed his personal thanks to all members of the Council and Committee for their unvarying courtesy and support. He much regretted the necessity of leaving the service of the Association but had the satisfaction of knowing that work in all its branches was proceeding smoothly, and that many important results are within sight. Dr. S. G. Barker, D.I.C., A.Inst. P., head of the Association's Physics Department, has been appointed to succeed Mr. Bliss as Director of Research.

Cotton Growing in Uganda

Sir William F. Gowers, Governor of Uganda, was the principal guest at a luncheon given by the British Cotton Growing Association at Manchester on the 5th October. Lord Stanley presided and commended the work of Sir William Gowers, whose appearance in Northern Nigeria coincided with the beginning of the work of the Cotton Growing Association in that country.

Sir Wm. Gowers emphasised the importance of Africa as a consumer as well as producer, but said there must of course be production to secure consumption. Fortunately cotton was probably the best single crop on which Uganda could rely. In 1911, some 9,000 bales were produced and there was steady increase up to the war. By 1921, the output was 47,000 bales; in 1924 the yield was 124,000, and 196,000 in 1925. There was a larger acreage in 1926, but climatic conditions were unfavourable. Up to end of August the amount was 170,000, and the total should reach 180,000. He must admit the danger of the drop in price of American cotton, which would be disappointing to the native in Uganda. The probability was, however, that in the long run it would pay the Uganda native better to grow cotton than any other crop, though it might take him the longer to realise the fact if prices remained at a low level. He (Sir William) believed it was possible for the Protectorate to supply 500,000 bales of cotton per annum, and even within four or five years 350,000 bales might be reached.

Institute Membership

At the September meeting of the Council of the Institute, the following were elected to membership—D. N. Aspden (Warehouse Master), Binnyston Gardens, Bangalore City, India; Christopher Barrow (Technical Chemist), 37 Rowland Street, Beswick, Manchester; Harry D. Belland (Superintendent), Dominion Textile Co. Ltd., Dominion Cottons Branch, Verdun, Quebec, Canada; Benno Borzykowski (President of Borvisk Company), 78 Rue de Provence, Paris, France; Thomas E. Craven (Textile Instructor and Lecturer), 83 Grafton Road, Keighley; Howell K. Hallett (Cotton Manufacturer), Kendall Mills Inc., Paw Creek, N.C., U.S.A.; John Kenyon (Mill Manager), The Villa, Green Lane, Leigh; Joseph McIsaac (Principal, Textile School), Wilts. County Textile School, Trowbridge, Wilts.; Benjamin Musgrave (Yarn Merchant and Agent), Wensley Villa, Fagley, Bradford, Yorks.; Pierre Leblan (Cotton Spinning Mill Manager), 87 Rue de Lannoy, Lille Fives, France (Nord) ; Henry O. Richardson (Works and Analytical Chemist), Ashworth House, Ashworth Road, Dewsbury, Yorks.; E. R. Scragg (Silk Textile Machinist), c/o Ernest Scragg & Sons, Ltd., Macclesfield; H. Sutcliffe Smith (Executive Director, Bradford Dyers' Association, Ltd.), Ingerthorpe Grange, Markington, near Harrogate; Frank Stoyle (Chief Chemist), c/o The Bulmer Rayon Co. Ltd., Stowmarket, Suffolk; Zoltan Szaloki (Assistant

Textile Professor), 1 Karap utca 13, Budapest, Hungary; W. Arthur Turner (Secretary), The Worsted Spinners' Federation, Ltd., 20/26 King's Arcade, Bradford, Yorks.; Alfred Wilman (Silk Noil Spinner and Manufacturer), Station Mills, Hadfield, near Manchester; Harold L. Johnson (Hosiery Manufacturer; in charge of Cutting Department), 3 Gedling Grove, Nottingham; Charles J. Wright (Assistant Chemist), 44 Kilnside Road, Paisley, Scotland; A. L. Patterson (Research Physicist), Kaiser Wilhelm-Institut fur Faserstoffchemie, Faradayweg 16, Berlin-Dahlem, Germany.

COMMUNICATION

To the Editor

"The Hygroscopic Properties of Colloidal Fibres and their Relation to Technical Processes"

Sir

In the August number of the *Journal of the Textile Institute* (P137) there appears the report of a paper read at the recent meeting of the British Association by Messrs. Barker, Hirst, and King, in which it is stated that the authors "Presented a paper . . . in the course of which the theory of elasticity of colloidal fibres was developed." May I be allowed to point out that this wording is misleading ? It implies that the paper is an original contribution to the theory of fibre elasticity (or an account, at least, of the authors' previously published original work), whereas the theory described by the authors was put forward and developed by me more than two years ago.[1,2] The omission of any indication that this portion of the paper is not the authors' own work is regrettable since it may lead to wrongful attribution in other journals.

There is another point which calls for comment. The authors attempt to correlate the various phenomena (elasticity, heat of wetting, swelling, &c.) and arrive at the conclusion that they "are explained by assuming the keratin substance of wool to be of the type of structure observed in dried gelatin jellies, rather than to the surface area or due to any grosser heterogeneous structure such as would be involved in the individual cells of scales or cortex, or the easily observable pores found by Mark."

So far as the elastic properties are concerned, this conclusion is extremely dubious. It is true that a fine-grained heterogeneity is capable of giving rise to the peculiar "elastic after-effect" exhibited by fibres, but it by no means follows conversely that any particular instance of the effect is necessarily due to the fine-grained heterogeneity. My theory postulates a heterogeneity which is most simply described in terms of an elastic and a viscous phase, and makes no attempt to specify more closely the precise nature of the phases. A general theory of fibre elasticity can do no more than this, since different fibres show such great differences of structure. Thus the cotton hair is quite different biologically from the wool fibre; and a filament of artificial silk has no visible structure at all. Further research may reveal new facts by means of which the theory can be developed further for specific fibres, but it is highly probable that the line of development will be different for each fibre.

The evidence available at present points to the physical properties of the wool fibre being dependent upon a heterogeneity more complex than that of gelatin jelly. The two-phase theory has been recently applied to the study of the elastic properties of rods of gelatin jelly by Poole[3] who shows that such rods when loaded extend in a manner characteristic of the most simple conceivable type of two-phase system. As I had shown previously, the mode of extension of a wool fibre indicates a complex type of heterogeneity. Moreover the viscous phase itself behaves as a gelatinous fluid, and may possess a complex structure.

The above considerations throw considerable doubt on the above conclusion put forward by Barker, Hirst, and King, and indicate that it is by no means

safe to neglect the "grosser heterogeneous structure" of fibres. In the case of the wool fibre a more elementary consideration is that a wool fibre is far from being perfectly soluble in boiling water.

AUTHORS' REPLY

By the courtesy of the Editor we have seen Dr. Shorter's criticism of the report of our paper, and are surprised that he has thought fit to use for criticism a brief note of the paper, when he has neither seen the original in extenso, nor was he present at the British Association meeting. In the original paper, which is now in the press, we have duly acknowledged authorship of every point both in the text and in the bibliography.

With regard to the scientific criticisms raised, we feel that our complete paper, when published, will be the most effective reply.

Leeds, 2nd October 1926.

REVIEWS

The Finishing of Woven Fabrics. By Roberts Beaumont, M.Sc., M.I.Mech.E. Scott, Greenwood & Son, London. Price, 15s.

The publication of a second edition of this work is a tribute to its excellence. Since the late Roberts Beaumont originally wrote this book, a considerable amount of investigation and research has been undertaken. New knowledge had been obtained in respect to the crabbing, lustring, and finishing of wool fabrics; detergents and agents used for scouring and milling, and also in respect to the properties of wool fibres. New theories regarding the phenomena of fibre movements and wool felting during wet finishing processes have been advanced. It is pleasing to note that these matters have been thoroughly considered and dealt with. The new publication in addition to being completely revised contains two new chapters, this having been done very efficiently by Mr. Alex. Yewdall, of the University of Leeds. The work is well written and illustrated, and provides an excellent treatise on the theory and practice of cloth finishing. —E.M.

Handbook of Weaving and Manufacturing. By Henry Greenwood. Published by Pitman & Sons, Ltd. (124 pp. and Index. 5s. net).

The contents of this small treatise indicate its very wide scope, for it treats of the subject of weaving and, in fact, of all other allied subjects literally from A to Z, and in alphabetical order after the manner of a dictionary or encyclopedia. Some idea of the scope of this book will be gathered from the following items, which are a mere fraction of those given in the complete contents—"Yarn and Cloth Calculations; Types of Yarns; Conversion Tables; Loom Drafts; Tie-ups and Peg Plans; Details of all Manufacturing Machines, with notes on Mill Driving; Humidifying; Maintenance of Hygrometers; Ventilation; Fire Appliances; Useful Tables," &c. In a very short Preface, which is a model of brevity, the author says—"This small treatise endeavours to put in concise form, practical information suitable for students, weavers, overlookers, managers, and others engaged in the textile industry," and concludes with the hope "that the practical information contained in this book will be of use to the industry, and fill a gap in modern textile literature."

The book certainly contains a vast amount of information and useful data, but its description as a "treatise" is a misnomer inasmuch as it does not expound or "treat" of the various subjects after the manner of a class text-book. In the present volume, the various subjects are arranged in a more or less haphazard manner, so that it assumes somewhat of the composite character and style of the "Useful Compendium" or "Handy Book of Reference." The subject matter, too, is so very concise and condensed, and written in many instances in such a loose style of phraseology as oftentimes to defeat the author's aim. For though brevity is a commendable feature, still clarity of expression should not, especially in a "treatise" for students, be sacrificed to mere brevity. Information for students should be explicit and accurate, not vague or inaccurate as, unfortunately, is the case in several instances in the book under review. For example, on page 3, a type of artificial silk is given as "Viscous" instead of "Viscose"; nor is it a fact that "coco-nut fibre" is "from the hard shell of the coco-nut," but from the outer sheath or husk enclosing the shell. Strictly "Bump Yarns" signify counts below 1s and not, as stated on page 7, "counts usually 3s or below." It is surprising to find in a modern treatise (page 14), a "Yarn Warping Table" occupying nearly a full page that could have been filled with much more useful matter. In the "Conversion Tables" (page 38), it is unfortunate that the headings of columns 2 and 3, 5 and 6, should read "per Running" and "per Sq. *Yard*," instead of "Metre," an error which is also repeated in the example and answer given. "Pirn-warping" (page 56) should have been described as "Warp Pirning"; there is no such operation as the former. It is also misleading to repeat on page 56, as to state on page 53, that "pirn winding" is "to wind yarn from hank form on to a pirn for the shuttle," when it is commonly wound from all other forms of yarn packages. Also it is wrong (page 56) to define "reaching-in" as a "small machine for selecting the threads for the drawer-in," and "warp-winding" as "to wind yarn from beam or ball warp to pirns or paper tubes for the shuttle." Speaking of artificial silk, under "Weaving of Warp" (page 93), "the timing of the shed may be a little late to ensure the shed is open when the shuttle enters" should surely read "a little early." It is also wrong to say that "any undue stretch in the warp will show lack of lustre," although it is correctly stated under "Weft Winding and Weaving" (page 94) that "tight (taut) picks will show as bright picks." A little more careful editing and the correction of the errors such as those indicated above will enhance the value of this useful little handbook. —H.N.

Distribution of Textiles. Bulletin No. 56 of the Harvard Bureau of Business Research (Cambridge, Massachusetts, 1926. 196 pp. $3.50).

This study of the American textile industries is the work of a group of investigators connected with the Harvard Bureau of Business Research, but the survey was undertaken "at the request of men engaged in the textile industry and the funds for carrying it on were provided by an anonymous gift." Manufacturers and traders of all kinds in the textile industry gave generous help in the planning of the survey and the drafting of the schedules. The response to the inquiries of the field workers was very gratifying, and a large amount of confidential information was placed at the disposal of the Bureau. All this reads like a fairy tale to those who have attempted to carry out similar pieces of work in this country, where there is still such widespread apathy towards statistical studies of the textile trades. It is heavy uphill work to get our main body of textile industrialists even mildly interested in the collection of statistics. But the reading of this book leaves no doubt in one's mind about the value of such studies. The American textile producers have ample reward for their initiative in the precise information conveyed in this volume. We congratulate them and hope their example will speedily be followed in England. The study is confined to the distribution of woven fabrics, and shows the relative volume of textile goods flowing through the several channels of distribution. After a brief explanation of the reason for using the data provided by actual invoices of goods despatched through various channels, a detailed analysis is given of the results of inquiries relating to woollen and worsted fabrics, rugs and carpets, silk cloth and ribbons, and cotton fabrics. These results relate chiefly to the proportions in which goods pass from the manufacturer to wholesale piece merchants, the wholesale clothier or maker-up of garments, and the retail traders. In the

course of the analysis, much light is shed on the economic problems of the American textile trades. In common with this country, American producers are feeling the change in the social habits of consumers. The "style factor" is shown to be the predominant cause of the hand-to-mouth trading which has displaced the steady trading for a season in goods that could be produced in bulk in advance. The suspicion that American demand for both cotton and wool fabrics is tending to move on to cheaper ranges of materials is confirmed. The reduction in the size of orders placed with manufacturers which is becoming so marked a feature of our trade in this country is another reflection of the vagaries of fashion. Recriminations between the several groups in the industry are as frequent in America as they are here when the problem of adjusting price levels and cutting losses is under discussion. The retail trade with them, as with us, is apparently the main stumbling block to the rapid adjustments that are needed to maintain the flow of demand. These and many other points are raised. The chief inference drawn by the investigators is that manufacturing and marketing must be adjusted to the new tendencies in demand. Changes of style should be viewed as "a positive, sales-stimulating influence." Better marketing means better team work than we have seen in the past. Americans are telling of organising more co-operative selling and cutting out the waste entailed by elaborate competitive sampling and production over an ever increasing range of cloths and styles. We are also talking of the same thing in this country. But where we are compelled to walk and talk in the dark for want of accurate statistical information, our American competitors are able to walk and talk in the light shed upon their problems by such valuable studies as these produced by the Harvard Bureau.

—A.N.S.

The Testing of Yarns and Fabrics. By H. P. Curtis. London: Sir Isaac Pitman & Sons, Ltd. (pp. 161 and Index. 5s. net).

In an introduction to his work, the author states that it has been written specifically for those engaged in the manufacture, merchanting, retail sale, and use of textiles. With this object in view he has endeavoured to survey the field of textile testing, giving a general idea of the raw materials consumed in the industry, of the simpler chemical means used for their identification, and of the mechanical methods employed in determining quantitatively their physical properties. He has, however, overlooked the main consideration in the preparation of an elementary text book, namely, that accuracy is essential. One is astonished to hear, for example, that the central portion of the silk fibre is composed of *fibrion* (p. 25), that if wool be exposed to the atmosphere in warm, dry weather, it contains from 30 to 50% of moisture (p. 31), that weak sulphuric acid stains cotton blue (p. 33), and that moisture tests are usually carried out at 55° C. (p. 65). It is inaccurate, also, to say that Primuline may be diazotised with sodium *nitrate* and hydrochloric acid (p. 95), that "common yellow" is otherwise known as *chrysophimne* (p. 95), and that mercerised cotton (p. 101) and starch (p. 102) gives a blue colouration with potassium iodide solution. The author apparently believes that chloroform is a highly inflammable substance, and accordingly gives directions concerning its use (p. 104). It would appear unnecessary to recommend "gramme weights and metric weights" as advisable for use with the balance (p. 45), and he has his own ideas concerning the most convenient method of using a desiccator (p. 90). On account of its mistakes and mis-statements, he should revise this book as soon as is conveniently possible.

—F.L.B.

GENERAL ITEMS AND REPORTS

Manchester Textile Exhibition

This exhibition, held at Belle Vue, was an important item in the Civic Week programme and proved well worth a visit. Over a hundred firms took space and were representative of the following sections of the industry—Engineering, spinning, manufacturing, and merchanting. In addition, stands were occupied by newspapers and textile journals, and there were also displays of work done by the students of various technical colleges and schools. As is usual in present-day textile exhibitions, artificial silk played a very important part, and many varied and beautiful exhibits were to be seen, both in piece goods and made-up garments. A model of the Port of Manchester formed the exhibit of the Manchester Ship Canal Company and attracted a great deal of attention. In connection with the exhibition, the British Model House, Ltd., held a mannequin parade in a specially-constructed theatre three times each day, and very full houses testified to the popularity of the feature. These parades were under the management of Mr. Arthur White, to whom every credit should be given for assembling a very attractive array of frocks and coats, and for the manner in which they were shown. A special feature of the parade was a display of period dresses—eighteen in all—dating from the eleventh to the nineteenth century, which gave a very clear idea of the evolution of fashion. Although some of the exhibitors had rather marred the effect of their stands by overcrowding, thus giving the impression of "heaviness," the exhibition as a whole was extremely good and, being of a general textile character, was of interest to all visitors. The organisers of the exhibition, *The Manchester Guardian Commercial*, are to be congratulated on a contribution well worthy of Manchester's Civic Week.

Textile Exhibition at Leicester

Since the last exhibition organised by the *Textile Recorder* at Leicester in 1923, there seem to have been few innovations in knitting machinery. Some minor novel textile accessories and small improvements to standard types of machinery, however, provided a note of freshness at this year's exhibition at Leicester, 8th to 23rd October. Perhaps as interesting exhibit as any was a fast-running ribbon loom made by a foreign firm, which was weaving unsized artificial silk yarns, with no extra twist, at a rate of 700 picks per minute. A simple device enabled the operator to change or vary the number of picks per minute, with celerity, accuracy, and ease. Worth mentioning also was an improved testing machine for stretch and breaking strength of artificial silk yarns, the findings being recorded automatically on a graph. A most ingenious jacquard embroidery machine was displayed on one of the stands. Using the normal selection device actuated by a continuous card, and applying it to control the movement beneath the embroidery needle of a fabric-holding frame, this machine, which, apart from the jacquard mechanism, resembles the ordinary sewing machine, was perhaps the most interesting novelty in the exhibition. As was natural at an exhibition in the Leicester district, a fair proportion of the floor space was given over to knitting machinery, most of which, apart from the more general use of jacquards in both flat and circular machines, was much the same as that shown three years ago. In the fabrics section there were several very beautiful and interesting collections of artificial silk yarns and fabrics, and it was noteworthy that practically all the English producers, together with agents of some important Continental producers, were represented. When it is remembered that at the last Leicester Exhibition only one British firm of artificial silk producers had an exhibit, whereas to-day no fewer than five have taken space, an interesting sidelight is thrown on the development of the artificial silk industry. Many firms of spinners exhibited mixture yarns of cotton or wool and artificial silk, and there were not wanting examples of fabrics of cotton and acetate silk, wool and viscose, which had been cross-dyed—a practice which may have been somewhat overdone. One important inference might be drawn from a visit to the exhibition as to tendency with regard to the character aimed at in production of both yarns and fabrics containing artificial silk. There seems to be a definite movement away from lustre emphasis and distinct effort in the direction of approximation to natural silk from the point of view of lustre. Mixture yarns, at any rate, were much more in evidence than previously, and this may have been due to the movement already indicated.

Collaboration and Distribution of Wool Textiles

A meeting of the Bradford Textile Society was held at the Midland Hotel, Bradford, on Monday, 11th October, when Mr. Arthur Hitt, the President, delivered the lecture. Mr. W. A. Elliott presided. Mr. Hitt said that they had had men in Yorkshire who, by great initiative, highly-trained technical skill, and all-round efficiency, had made their names familiar all over the world, but they had concentrated almost entirely on the side of production. Twenty years ago it might have been said that if we made the right cloths at the right price they would sell themselves. That did not obtain to-day. Our greatest problem was not so much production as marketing. He suggested that what was wanted was collaboration with retail distributors and the buying public; some form of co-operation in selling; and collective use of publicity. He suggested that the trade collectively should form an Advisory Council, in which the buying public and the wholesale and retail distributors should join with the manufacturers, in order to get a forecast with regard to probable fashions, make of cloth, colour, &c., some months prior to the season starting. That would eliminate the waste of experimental patterns and accumulated bad stocks which were costly to manufacturers, merchants, and dyers. The public, because of it, would have better value, and production and demand would be kept in tune. There were probably two hundred mills in Bradford trying to make the same or similar cloths, with two hundred selling organisations. This involved enormous waste in experimental patterns, giving the dyers many thousands of patterns to dye every year, the majority of which were never followed by bulk business. This waste would never help us to capture markets, and such methods did not mean economy in either production or distribution. How much better if these mills were formed into groups, allocating one cloth to one mill, and by something like mass production lower the costs and economise distribution. Bradford cloths were now filtering through to the public unrecognised by that public. Neither merchants nor retail distributors were functioning in the sense of linking up the British maker of the cloth with those who wore it. Nothing had been more revolutionary during the last twenty years than the increased influence of publicity. Its demands alone must have the tendency to drive firms into groups, as no concern could adequately finance it in addition to other distributing costs. Applying publicity to the Bradford trade involved the fundamental recognition of the cloths by the public when it saw them. A selvage controlled by the Bradford Chamber of Commerce was one of the suggestions made. Failing this, cloths could be offered under registered names, but whether selvage or name, propaganda was essential. The future outlook seemed to depend on our recognising the public willingness to buy Bradford goods; the merit of the goods; the pressing need to secure greater prosperity for the industry. All these were contributing factors to collaboration, markets, and distribution.

Mr. W. H. Suddards said collaboration must have a much wider scope than the mere object of raising prices. Unless it was going to improve methods of production and develop greater initiative and greater economy in production, it would be useless. The idea behind collaboration must not be that it would be more profitable to the individual Bradford manufacturer; it must be of benefit to the nation as a whole.

Mr. Wm. Wright said that assuming they could manufacture the right type of cloth for certain markets and were willing to give credit, there were still difficulties which the exporter had to meet. The first of these was the price factor. In that respect they would be the gainers when countries with depreciated currencies were brought on to a gold standard. There was also the difficulty of the reduced buying capacity of the foreigner. A good deal could be done to stimulate that buying capacity by indirect methods. For instance, China, with 400 million people, bought only twice as much as the Argentine, with 10 million people. If a vast country like China could have its purchasing power developed by building railways and so forth, she would become a very powerful customer.

Mr. A. M. Chapman said that what Bradford wanted was a big volume of trade on standard cloths. The novelty trade would not keep them employed.

A vote of thanks was accorded to Mr. Hitt, on the motion of Mr. John Mason, seconded by Mr. J. Lester.

THE JOURNAL OF THE
TEXTILE INSTITUTE

Vol. XVII NOVEMBER No. 11

PROCEEDINGS

ANNUAL CONFERENCE OF THE TEXTILE INSTITUTE

At Buxton (Derbyshire), 20th, 21st, and 22nd October 1926

Postponed from Whit-week last, the Annual Conference of the Institute took place at Buxton on the above-named dates. Except that postponement probably accounted for the fact that the number of members in attendance was not quite so large as usual, the attendance under prevailing conditions was quite satisfactory, and the fixture was most successful. The accommodation and facilities available at Buxton for conference purposes are excellent, and the visit to this Derbyshire health resort was thoroughly enjoyed. The programme opened with an evening reception at the Town Hall by invitation of the Mayor and Mayoress of Buxton (Alderman and Mrs. T. H. Cooper), and about 150 guests were present. At a suitable interval in the programme of vocal and instrumental music, the Mayor expressed a hearty welcome to the visitors, and regretted that it had been necessary to postpone the conference from Whitsuntide. At that time they little thought that as late as October the country would still be in the throes of the unfortunate coal industry dispute. He trusted that the Institute's visit to Buxton would prove both useful and enjoyable, and that visitors there for the first time would find sufficient inducement to return on some future occasion.

The President of the Institute (Mr. William Howarth, J.P.), on behalf of the visiting members and friends, expressed warmest thanks to the Mayor and Mayoress for the entertainment and hospitality afforded and for the generous manner in which the municipal authorities had helped in regard to the arrangements for the conference. With the Mayor, he regretted the cause of the postponement of the fixture. So far as the textile industry was concerned, the Institute was a movement in the direction of higher efficiency, and the bringing together of representatives of various branches of the industry at that conference was calculated to strengthen the Institute and to promote good feeling between all sections.

The conference met on the Thursday morning (21st October) in the Town Hall, when the President of the Institute occupied the chair, and was supported by Messrs. John Crompton, W. Frost, T. Fletcher Robinson, and E. T. Holdsworth. Introducing Sir William Bragg, the contributor of the annual Mather Lecture, the President said—This lecture was inaugurated in 1919 not only in recognition and appreciation of the splendid services and generosity of the late Sir William Mather, in the capacity of President, but in order to advance the standard of Institute lectures. Sir William Bragg is a Cumberland man whose name is known to men of science in all parts of the world for the wonderful way in which, with his son, who is the Langworthy Professor of Physics at Manchester University, he has used X-rays to explore the structure of crystalline bodies. The discoveries of father and son justly merited the award of a Nobel prize in 1915.

During the war they applied themselves to the important problem of sound ranging, and so valuable were their services that we may rightly say that few men more thoroughly deserved the order of Knighthood which His Majesty the King was pleased to confer on our lecturer. Sir William is now Director of the Davy-Faraday Research Laboratory, and Fullerian Professor of Physics at the Royal Institution. In these honourable appointments, he is walking worthily in the steps of a succession of brilliant men, and we are confident that history will accord him a place equal to that of Davy or of Faraday. Like Faraday, Sir William has the supreme gift of being able to make plain the deep things of science. His Christmas lectures to juvenile audiences—"Concerning the Nature of Things" and "Old Trades and Modern Science"—and his talks from our broadcasting stations have been ample proof of this skill, and we men of the spindle and the loom are shortly to be given another. In the past year or two, Sir William has applied his analytical methods with the X-rays to the study of organic chemical substances, and had thus come into the field where he makes direct contact with the textile industries. Very far-reaching results can be expected to follow investigations into the intimate structure of textile fibres, and I am sure we shall all profit by the review of the progress already made in this field which Sir William is now about to give us.

THE MATHER LECTURE

THE FINE STRUCTURE OF ANIMAL AND VEGETABLE SUBSTANCES AS REVEALED BY X-RAYS

By Sir William H. Bragg, K.B.E., D.Sc., F.R.S

In the year 1912 Laue suggested, and Friedrich and Knipping carried out, an experiment of fundamental importance. It proved that X-rays could, under the right conditions, be diffracted in the same manner as light waves. The diffraction of light is a fact of common observation, manifested in the haloes that surround luminous objects viewed through a cloud of small particles, as when the moon is seen through a misty atmosphere, or again, in the colours of insects, beetles, and birds to which Nature gives some permanency by forming them, not from pigments or dyes, but from the diffracting effects of an ordered array of fine points or fibres, or scales. While the diffraction of light is to be observed at all times and in all places, the diffraction of X-rays requires unfamiliar mechanism for its production and for its detection, and has escaped observation until now. Our past ignorance is easily understood. The rays themselves consist of waves ten thousand times shorter than light waves; though their nature is absolutely the same, and if light consists of waves travelling through an ether which fills all space, so also must X-rays consist of waves travelling in the same medium. The only difference is in the dimensions of the waves. But that difference removes the rays far from the range which our eyes are formed to perceive. The range of vision by eye is very narrow; the wave must be distinctly less than the ten-millionth part of a centimetre if it is to make any impression on the eye, and the shortest wave that can be seen—that which gives the sensation of violet—is about half the length of the longest, which is red. Within this range are all the waves of visible light; with these waves Nature has made it possible for all conscious beings to be aware of their surroundings—to have eyes and to see.

Outside this range we have no direct means of detecting ether waves except that we become conscious of somewhat longer waves by the sensation of warmth which our skin can feel. It is no wonder, therefore, that only in recent times have we been able to extend our natural powers and, by means which we have not received as a natural endowment but have discovered for ourselves, have

learnt to produce and detect and make use of waves outside the visible range. Long waves, far outside that range, are used now in wireless telephony, thanks to the discovery of the valve. The extremely short waves which we call X-rays lie on the other side, and for some thirty years, ever since Röntgen's original discovery, we have known how to produce them, how to detect them, and how to make use, chiefly for medical or surgical purposes or in the examination of materials, of their powers of penetration which differ so strangely from those of light. Until Laue's experiment we were not able to assert without question that they were waves at all; we had them at our command without being aware of their nature. The essential importance of Laue's experiment consists in the first place of the resolution of this doubt. But it goes far beyond this point. The very method by which the uncertainty has been removed has opened up wide fields of usefulness of which the existence had never been suspected. It is my object to-day to explain this matter very briefly, and in doing so to speak especially of those portions of the new field of inquiry which may be of interest to this Conference

The diffraction of light waves serves as a useful analogy if we wish to appreciate the principle of the new methods. The essential point is that in any case of diffraction it is always possible to draw inferences from the observed result as to the nature of the cause. If, for example, we observe the width of the moon halo we can calculate the average size of the particles in the air which produced it. If we take proper note of the colour of a butterfly's wing we can determine the spacing of the scales. In the more complicated case of the diffraction effects seen in the microscope, we may infer the form of the objects which caused them, although they are so minute that their outline cannot be observed directly—and this is the basis of a well-known and very important use of the microscope.

Now in the case of the X-rays, the diffraction effects are produced by the ordered arrangement of the atoms in a crystal, and the study of those effects tells us about the arrangement. The experiment is simple enough in conception, though the technique may sometimes be difficult. The interpretation of the results of the experiment is sometimes easy, sometimes not. When, for instance, we pass a fine pencil of X-rays from an ordinary X-ray tube through a thin plate of rocksalt, and receive the transmitted rays on a photographic plate, we find, after development of the plate, not only one spot in the centre of it where the original pencil has fallen, but also a very large number of weaker spots ranged symmetrically round the first. These extra images are due to the diffracted rays. Their position on the plate and their relative intensities furnish a mass of accurate numerical results from which it is possible to determine the structure of the crystal and the relative positions of the atoms of which it is composed. In the case of rocksalt, the problem is simple and the structure of rocksalt was one of the first to be unravelled. Since that time many more complicated solutions have been effected, but great numbers of crystal structures are yet awaiting their conquerors.

There is, in fact, a new game to play. With a little patience it is possible to acquire the experimental skill which is necessary for the production of the X-ray photograph of a crystal. It is not so difficult to build up the apparatus, to set it going with some small crystal or mass of powdered crystal in its place, to watch it for the necessary time (an hour or part of an hour, or several hours, as it may be), and then to develop the plate and observe the pattern of spots; and there are hundreds of thousands of known crystals which no one has yet treated in this way. But it is a very different thing to interpret the observed results. The position of each spot on the plate can be measured with great accuracy; its intensity can be estimated within certain limits. In fact, a mass of informing details can be obtained, of which the accuracy is no illusion because the measurements bear the most exacting repetition. We do not, however, know yet how to use it all.

Certain results can be immediately obtained which show an almost unexpected simplicity in many of the natural structures. We can find at once the size of the unit of the pattern; in a large number of cases it contains two, three, four, or more of the molecules which the chemist has taught us to recognise. This is the first and generally the easiest step in the interpretation. It always seems to me that there is something of extraordinary interest in this determination. When Nature forms the solid body she takes a certain number of the molecules with which our examination of substances in the liquid or gaseous state has made us familiar, and builds them together into the unit of pattern. We can always find out how many of these molecules she has taken for the purpose—generally quite a small number. That is one of the easy steps in the analysis. Moreover, she uses them all in the same way in a very large number of instances, though we have found some exceptions. This point is not, it may be, readily appreciated without some consideration. In the packing of sardines, for example, half the fish lie one way, the other half lie heads to tails with the first; the fish are therefore divided into two sorts so far as arrangement goes, and we must take one of each kind if we are to represent the conditions completely; in other words, the unit of pattern contains two fish. But there is no difference in the relations of any fish to its neighbours, no matter from which kind it is taken. It would be easy to imagine a more complicated packing of the fish; we might, for example, have alternate layers at right angles, thus having four kinds or orientations, and the representative unit of pattern must contain four fish. And again, we might have some layers with all the backs of the fish pointing one way, and an equal number of balancing layers in which the backs of the fish pointed the other way, and in this way the unit of pattern might be still more complicated. And if we might imagine each fish to be differently marked on its two sides, we might increase our complications yet further by requiring or by not requiring that there should be equal numbers of the two kinds. Just so, Nature arranges her molecules in her crystals, and it is a striking and simplifying fact that it usually is the molecule which she treats in this way—not some entirely fresh arrangement, such as the taking of the atoms of two molecules and putting them together in a new way to form a molecule which is not exactly two old molecules combined, as if two sardines had been remodelled into one pilchard. I use the word "usually" because we can find quite a number of cases in which remodelling has taken place, for example, in α-naphthylamine or in fumaric acid.

All this variety of arrangement in the crystal can be detected by the X-ray methods; we can find not only how many molecules are used in forming the unit of pattern, and what is the distance between a molecule in any one unit and a similar molecule in any other unit, but also we can find out what we may call the system of packing. This is an important step towards the full knowledge of the structure of the crystal.

But it is very far from being the whole story. We have still to find the position of every atom in the molecule, not only in relation to the other atoms in the same molecule, but to the other atoms in the other molecules in the unit of pattern. Here is the greatest difficulty of the problem. It is not that we have not got enough experimental facts: we have an ample sufficiency. What we lack is skill in interpreting them. But this latter grows every day. When the first few simple crystal structures were resolved some twelve years ago, it seemed that the vast bulk of the known crystals would be far out of our reach. And now fresh solutions appear continually, and complicated structures have yielded to the incessant labour of quite an army of researchers in various parts of the world.

But, we may ask, of what nature is this new information? Chemistry has taught us the composition of the various molecules and their probabilities of mutual action and rearrangement if they meet each other; we have learnt to measure the emission and absorption of heat when such reactions occur; and so we have learnt to understand and to foretell the consequences of these meetings. What does this new knowledge tell us?

The answer is that we are informed of the structure of solid bodies. Now the properties of solids are of the greatest interest and importance; ourselves and the things that we handle and deal with every day are largely solid. The properties of solids—rigidity, tensile strength, extensibility, heat capacity, optical powers, and very many others—are properties of the molecules when bound together, and are to be associated with this binding. There is no arrangement in the molecules of a gas or a liquid; the form of the molecule is of importance, of course, for the whole range of stereometric chemistry is witness to the fact. But the arrangement of the molecules in the crystal is a new factor in the situation, giving birth to the well-known properties of the solid, allowing the molecules to exert their mutual forces in a new way with entirely new results. All the properties of solids must eventually be explained in terms of the arrangements of the atoms and molecules which they contain. Arrangement is the especial feature of the solid, and those properties which are characteristic of the solid are due to it. It might be argued that there may be amorphous bodies which have no arrangement and yet are solid. But the evidence is rather on the negative side. Great numbers of substances are found to exhibit crystalline structure of some sort, when carefully examined, though there was no evidence of the fact until the X-rays revealed it. They may and often do consist of aggregates of minute crystals entirely beyond the power of the microscope to detect, but plain to the X-rays. If the crystals are very small, consisting of only a few molecules, even the X-rays, in the present state of the technique, may fail; but the boundary between the arranged and the completely disarranged is very hazy and tends to disappear. The fact is that arrangement is, so to speak, the natural state to which all things tend, though there may be hindrances of indefinite duration. Chemistry has dealt with the properties of fluids and liquids—not with those characteristics of solids. In fact, the methods of chemical analysis generally begin by destroying the ties that form the solid, and in so doing removing the very essence of the solid state. Only of recent years has it become necessary to take into account the nature and the influence of the surfaces of solids where the arrangement characteristic of the internal structure comes to the surface—in the literal sense. It may well be and doubtless is the case that the surface disposition of the atoms is modified by their partial freedom from the restraints which within the substance surround each atom, or by the adhesion or absorption of strange atoms. In this way the orientation or even the forms of the molecules may be modified, and their activities may be cloaked more or less; as we may say, their catalytic properties may be altered. These surface actions have acquired enormous interest in recent times, as we all know. The more we learn of them, the more we are impressed by the part they play in the processes of the world. Yet, after all, the bodies that act on one another, and in so doing continue the world history, are many of them solids and can act at their surfaces only. The point is that the disposition and orientation of the molecule on the surface is of vast importance, and we shall not understand this vital matter until we first grasp the simpler thing, viz. the internal arrangement in all its regularity. We shall then be in a better position to appreciate the more complicated state into which the simpler falls when outside agencies work upon it at the body surface.

It is here that chemistry is, so to speak, feeling its way into the solid body. The liquids and gases which have necessarily been the main subjects of inquiry hitherto have come up against the solid and felt its influence; and now the X-rays have come to tell us what is behind this surface, in regions where new rules are in force and govern the manifestation of new properties, those namely which are characteristic of the solid. The vast range of solid substances now lies open to a far keener examination than it has ever received before, and already some progress has been made.

The simplest of all bodies is the single crystal. That is somewhat curious because at one time we used to think of the crystal as the complex, in contrast

with the isotropic solid which had exactly the same properties in all directions. But the properties of such a solid are only to be secured by an averaging process—by piling together a number of minute crystals having all manner of arrangements. Of course, as has been already said, we can conceive of an entirely disordered arrangement of molecules, but as a matter of fact such an arrangement has not been actually proved to exist, and it may well be that there is some completed arrangement even in what we think to be a quite amorphous body.

The perfect crystal is very rare. Perhaps the diamond alone deserves the title of all the crystals we know, but it is not likely that one substance should be so completely differentiated from all others. Iceland spar is somewhat inferior to the diamond, in that the X-rays show it to be a mass of smaller crystals slightly varying in orientation. Rock-salt is much inferior; the disarrangement of the various small crystals of which it is composed is very obvious under the X-rays; and other bodies range themselves in various degrees of perfection, until we come to those in which the X-rays can barely detect the existence of any arrangement at all. It is common to find substances in which minute crystals are distributed in some containing medium; cotton and woollen fibres are examples of this condition, and are naturally to be chosen as illustrations on the present occasion. Sometimes the degree of crystallisation varies with circumstances. A most remarkable example is to be found in the case of india-rubber, which has lately been carefully examined by Katz and others. It has been shown that in its unstretched state there is no arrangement which the X-rays can detect, in the present state of the technique, but under tension, crystals form rapidly until, when the rubber is completely stretched, a condition which we all know from experiment, a very large, perhaps complete, conversion into crystals has taken place. With relaxation the crystalline arrangement disappears again.

It is a most remarkable fact that the minute crystals which are often found to be distributed through the body of a material show some regularity of arrangement. When it exists, we naturally look for its origin in some predisposing cause, and the nature of the cause is suggested by the nature of the regularity. Such a state is often found, for example, in a metal, and proves to be the result of some mechanical treatment. The crystals do not point every way; some one direction is found to be related more or less closely to a direction of rolling or drawing. In the same way the "crystallites" of animal and vegetable substances show some relation to the direction of growth as well as to the direction of any mechanical strain.

Now if we remember that all the physical properties of a fibre depend on the arrangement of its constituent atoms and molecules, and that the incipient crystallisations or crystallites are features of this arrangement, it must appear that the whole matter is worthy of serious study. What will flow from it no one can foretell. We can only argue by analogy or from extrapolation. Chemistry has studied the individual molecule and the reaction of molecules when they move, separate and free, in the liquid or gaseous state. The results are clear. What shall we perceive when we can see clearly the details of the arrangements that make the solid? We cannot prophesy; we can only expect.

It becomes, I think, an obvious task that we should examine by the new methods all the fibres and other substances on which our textile industries are founded; that we should see what such an examination has to tell us of the internal structure of the fibre. We should find out whether the X-rays can follow the changes that fibres usually experience in manufacture or under any treatment; we should want to know not only all the complicated and very important actions and dispositions in the interior, but also the nature and properties of the surface since these properties are so important in relation to such processes as, for example, the absorption of a dye.

We have not, I am bound to say, done much in this country. As you may know, the methods of X-ray analysis were first devised and used by ourselves,

and work in this direction is steadily proceeding in England. But the special application of the new methods to the textile problem has been conducted abroad, mainly in Germany, especially at the Kaiser Wilhelm Institut für Faserstoffchemie. The results obtained in these studies are already proving to be instructive and promising in the highest degree. They may not be immediately applicable to the solution of technical problems, but their future value is none the less likely; the whole matter is only in its preliminary stages. We have to think of the future and must put up with the delays of growth. What has been learnt must already be considered as indicating the promise of the method, as showing that new powers are in our possession. We know well from past experience that when a new departure of this kind is made, the point which is finally reached is rarely to be imagined at the outset; that which we first imagine we are going to do with some new method often comes to nothing. We really cannot see far enough ahead. We are led on by the conviction that new light on what we are doing will always enable us in the long run to do better. Light, and more light, is what we should always ask for, not some definite technical achievement. Give us more light on what we do, and we can depend on our own perception and ingenuity to make the best use of it. It is in this spirit that we should consider what has been done and is being done in the application of the new methods to the study of textile fibres.

The earliest application of the X-ray methods to the study of fibres showed at once that there was something to be seen—that, in fact, there was something crystalline about them. Nature had been successful in arranging some parts of the fibre in a regular fashion. As the technique of the analysis has improved the results have become more and more definite, and it is now possible to obtain diffraction figures which are comparable in clearness of definition with those obtained from structures that are fully and obviously crystalline.

From these figures we learn a number of things. In the first place the fibre contains a multitude of fine crystals which not only possess in each case that regularity of internal arrangement which is characteristic of the crystal, but also possess some regularity of mutual arrangement. There is a certain line in each crystal which is directed more or less along the axis of the fibre. In some way, not understood, the growth of the fibre not only forms these crystals, but orients them in regard to this one direction. Otherwise their orientation is haphazard; they may take up any position about the unique direction. We know this from a peculiarity in the arrangement of the diffraction pattern which is easy to observe but too complicated to explain in the short time at our disposal. It can be illustrated by the accompanying figures. The first shows the diffraction pattern of ramie fibre, obtained by passing a fine pencil of X-rays through a bundle of parallel fibres, so that the pencil subsequently falls perpendicularly on a photographic plate. The pencil would make a very strong impression on the plate at the point where it strikes if it were not that a screen has been placed so as to intercept it. The effect would be so violent as to spoil the central parts of the plate for the reception of other and feebler impressions. The diffraction pattern consists of an arrangement of spots which is symmetrical both with regard to the vertical and the horizontal. The vertical line is parallel to the axis of the fibres.

The next figure is the diffraction pattern of a single crystal of sugar, but in this case the crystal has been steadily rotated during the exposure about an axis perpendicular to the X-rays and parallel to the plate. Here again the general features are the same, but the spots of the pattern have their own characteristic positions and intensities.

In the case of the single crystal of sugar no pattern is obtained without the rotation. If we could watch the spots forming on the plate, instead of having to wait for the action of the photographic developer, we should see the spots dropping into their places one by one as the crystal revolved. They may be considered to be due to reflection of the X-rays by various planes in the crystal.

It is a fundamental principle that the rays are only reflected by any plane within the crystal when there is the correct angular relation between the rays and the plane, a relation characteristic of that plane. Otherwise there is no reflection at all. As the crystal is revolved one plane after another comes into its correct position. If the crystal had not been revolved, one or two spots might have been formed accidentally on the plate, but there would be no complete pattern.

It was not necessary to revolve the ramie fibres, because all possible positions of the crystals were already represented by various members of the bundle. It is for this reason that the general characteristics of the two illustrations are the same. It is in this way that we learn that in the bundle of fibres there are crystals which all have one direction in common, but otherwise are in complete disarray.

It is certainly not surprising that in this way also we find a complexity in the structure of the fibres, because the fact has already been surmised for other reasons. The physical behaviour, and especially the curious laws of extension of the fibres, have led investigators* to suppose that there are two phases at least in the fibre—one possessing perfect elasticity and the other the viscosity of a liquid.

The next point for consideration is the size of the unit pattern. This can be deduced from measurements of the positions of the spots on the diffraction pattern. I shall not attempt to explain how this is done because it would take far too much time. I shall only state the results that Herzog gives (*The Journal of Physical Chemistry*, April 1926, p. 457) as the result of many measurements. The unit pattern is contained in a right-angled cell, the sides of which measure 8·60, 7·78, and 10·22 Angstrom units† respectively. If we calculate the volume of this cell and multiply it by the specific gravity of cellulose, 1·52, we find that the weight of the cell content is 1040×10^{-24} gr. Now the actual weight of the cellulose molecule is 162 times the weight of the hydrogen atom and can be readily calculated to be 270×10^{-24} gr. The weight of the cell is therefore very nearly four times the weight of the molecule, and we assume that there are actually four molecules in the cell, for the number must be an integer and the experimental errors may well account for the small failure to reach an integral value in the experiments and the calculations. This means that the crystalline structure is really simple, in that it is formed by the mere repetition of a fundamental unit of pattern containing only four cellulose molecules. A very large number of other substances have four molecules to the cell.

This same summary due to Herzog contains other conclusions of great interest, but I will only mention one or two. It is shown, for example, that in cellulose nitrate and in cellulose acetate the structure is very nearly the same as in cellulose itself; the unit cell has the same form and nearly the same dimensions as that of cellulose, from which it is deduced that in the conversion into the nitrate or the acetate the reaction is topochemical. The relative positions of the four kinds of molecules, and the way in which they lie up against one another so as to satisfy their complicated attractions, are little modified by the chemical change in the constitution of the molecules. It would be easy to understand that the change in configuration and nature would be so great that an entirely new pattern would be formed, having no relation to the old. But it is not so, and there must be a meaning in the fact which we cannot at present grasp entirely because we are ignorant on so many other points.

So also Herzog states, as further results of the X-ray investigations, that cellulose fibres obtained by the denitration of a cellulose nitrate, and from the hydrolysis of a cellulose acetate (both of them being prepared from untreated cellulose), give the diagram of the latter. On the other hand, cellulose regenerated from esters prepared from a mercerised cotton gives the diagram of cellulose hydrate.

*For example, Shorter. Transactions of the Faraday Society, 1924, **20**.

†The Angstrom unit is 10^{-8} cm.

One further deduction from these measurements deserves especial mention because it illustrates another of the powers of the new methods. Diffraction effects have always this property, that the greater the quantity and the higher the quality of the arrangements to which they are due, the more perfect is their precision. The diffraction grating used on the spectrometer is ruled with many thousands of parallel lines. The extraordinary sharpness of the line in the spectrum is due in the first place to the regularity and uniformity of the ruling. So also the sharpness and brilliancy of the halo that is to be seen round a bright point viewed through a misty atmosphere, or as in Young's Eriometer through a mass of fibres, depend partly on the number of particles or fibres, partly on the uniformity of their size.

The X-rays show the analogous effect. The spots on the photographs such as those illustrated, and the lines in some convenient forms of the diffraction effect are usually very sharp because the regularity in the crystal to which the effect is due usually extends over millions of units of the pattern. If, however, the number of units falls into the thousands or hundreds, the sharpness begins to fail; and it has even been shown by Scherrer and others that it is possible to calculate the average size of the crystallites in the fibre. Herzog thus finds that the average sizes of the crystallites of cellulose nitrate and of cellulose are about the same, each containing one or two thousand molecules; the size of particles in colloidal solutions of cellulose nitrate has the same value.

I have chosen this instance of the application of the new methods to the study of natural substances because it is related to those materials in which the members of the Conference are particularly interested.

But the methods have many other applications. In fact, so it seems to me, its universality is one of its greatest charms. All arts and sciences and industries employ solid substances, and their operations are dependent on the physical properties of solids. These properties depend, in their turn, upon the arrangement of the atoms and molecules, an arrangement which in the hands of Nature becomes surprisingly regular. Now the X-rays enable us to investigate all the details of the regularity as nothing else has hitherto been able to do. Thus the method has been applied to the study of the crystalline structure of metals, where, indeed, the relation between the crystalline condition and the physical properties has long been realised, though never could it be examined so thoroughly as now. A curious and more recent example is that of rubber. It appears that unstretched rubber shows very little regularity of arrangement, but that, as it is stretched, crystallites form and, in the end comprise, it may be, the bulk of the substance. When this point has been reached the rubber no longer extends so easily as at first. When the strain is relaxed the regularity disappears. The applications to biology are as yet very few and far between, though we know now the interesting fact that regularity of arrangement occurs in growing structures and is related to the direction of growth. This development of the subject is only just beginning. Another example is to be found in the remarkable conclusions of Shearer, Muller, and others, on the solid condition of long chain compounds. When substances of this kind, for example, members of the fatty acid series are pressed or squeezed, there is a rapid development of regularity in certain directions. The molecules arrange themselves in layers in each of which the long chain molecules stand side by side more or less normal to the layer. Sideways regularities are less readily developed, and are not so obvious on the photographic plate. The tendency of the molecules to pack more quickly and regularly in some directions than in others is witness to the fact that the molecule is to be thought of as having a highly irregular but definite and persistent form. Perhaps the point might be better expressed by saying that the molecule is surrounded by a very complex field of force, which when inter-locking with the fields of its neighbours will necessitate perfect alignments. We may learn more about these fields that bind solid bodies together by observing not only the finished result as in a perfect crystal, but also the incipient steps of crystallisation

when the forces of combination sort themselves out into those that must first be satisfied and those that must wait. It is these incomplete conditions that must interest us most. A complete and perfect crystal is inactive except at its surface; it is when crystals are forming or disappearing, when they are dispersed in some other medium or phase, and in active contact over large surfaces that their influence is great on the changes which we are concerned to watch. If Nature had thrown her molecules together in the solid as haphazard as in a liquid, or a gas, this new interest would not be ours. It is because regularity is so persistently aimed at and achieved, and because it is constantly breaking down and being repaired, and again because all the properties of solid bodies, so utterly important to us, are functions of this regularity, that we push on with our X-ray analysis, which depends on this regularity and furnishes the only efficient means of investigating it.

,, 7—Unstretched rubber (Hauser).
,, 8—Stretched rubber (Hauser).

Discussion

Dr. Shorter, in proposing a vote of thanks to Sir William Bragg, stated that he had special pleasure in doing so, since it was at Sir William's instigation that he first undertook research in textiles. It was at Leeds some ten years ago that Sir William was instrumental in inaugurating a piece of work which may be regarded as the starting point in Yorkshire of that movement which had culminated in the establishment of the textile research associations. With regard to the present lecture, one realised that though research in X-rays was a difficult matter, the exposition of the results of such research to a general audience was still more difficult. Of such exposition Sir William Bragg was undoubtedly the greatest master in England and, perhaps, in the whole world.

Dr. W. H. Gibson (Belfast) seconded and said the Institute had been fortunate indeed to secure the services of Sir William Bragg, whose choice of subject for the Mather Lecture was most gratifying, because a knowledge of the fine structure of fibres was felt by all investigators to be of prime importance. It was highly probable that such knowledge would have a profound influence on the investigation of textile problems. Personally, during twenty years of engagement in industrial research work, principally upon cellulose, he had always felt himself to be in the dark to the extent that little was really known of the fine structure of cellulosic fibres. The investigations now progressing would give the scientist working on cellulose a clearer mental picture of his material. Investigators lacked adequate tools for their work. Here was a new weapon of investigation which had already proved its value, and though it might not be universally used in industrial research laboratories, even a limited use would lead to the better understanding of textile fibres with a resulting improvement in our methods of testing and appreciation of the results of those tests. The work of Herzog referred to in the lecture, which showed that the size of the crystallites of cellulose nitrate and cellulose, and the size of the particles in colloidal solution of cellulose nitrate are about the same, confirmed the results of work on the viscosities of solutions of cellulose and cellulose nitrate, and served to explain the relationship

between a particular sample of cellulose and its derivative. Knowledge of this relationship had already proved of industrial value in the explosives and the artificial silk industry.

The vote was heartily accorded, and in reply Sir William Bragg said he had been most anxious to make the subject attractive to the practical man because it was upon the effective co-operation of the practical man and the pure scientist that progress depended. It was an extraordinary thing to find how completely the wonderful achievements of the past centuries were due to the close and continuous reaction between the labours of industry and the thought of the seekers after knowledge. Although X-ray work started in this country, the particular application of X-rays of which he had spoken came from abroad. We must not be content to allow others to make our inquiries into the structures of things we were handling every day. We must be in the forefront of such inquiries ourselves. He was inclined to believe that this work was only the beginning of something much greater and it was expected that very shortly at the National Physical Laboratory a department would be opened to study the new use of X-rays, particularly in relation to industry. This application of X-rays marked a new departure in the scientific world.

VISIT TO WORKS AND A SOCIAL EVENING

On the Thursday afternoon a visit of inspection of the works of Messrs. Ferodo, Ltd., at Chapel-en-le-Frith, took place, the journey being by motor vehicles. The party numbered about 50 persons. At the works small groups were formed and conducted over the various departments, offices, &c. The organisation associated with these works proved extremely interesting and the extraordinary variety of the products, together with the highly specialised plant and machinery associated therewith, were a revelation to many of the visitors. After the tour of the extensive works, tea was served in a delightful new dining hall and lounge facing a bowling green and outdoor games ground connected with the works. Mr. W. A. Horrocks, on behalf of Messrs. Ferodo, Ltd., welcomed the visitors, and Mr. John Crompton, as Chairman of Council, expressed the warm thanks of the Institute members for the facilities of inspection and the hospitality accorded to them.

In the evening, members and visitors were invited to attend a social gathering in the ballroom at the Buxton Hydro Hotel, the headquarters hotel for the purpose of the Conference. A programme of dance music and contributions by vocalists was presented, and a pleasant social evening was greatly enjoyed, ending with light refreshment served at the invitation of the President (Mr. W. Howarth).

CONFERENCE PROCEEDINGS ON FRIDAY, 22nd OCTOBER

The Conference resumed its sessions in the Town Hall on Friday morning, when the President again presided. He called upon Mr. J. A. Robertson, of Manchester, to read his paper.

CENTRALISATION OF ELECTRICITY PRODUCTION

By J. A. Robertson, M.I.E.E., M.I.Mech.E.

The advantages of a cheap and adequate supply of electricity for industrial, domestic, and other purposes are generally recognised, and in this paper it is proposed to deal only with the question of centralised production of electricity as compared with local generation, and to discuss briefly the far-reaching proposals of the Report of Lord Weir's Committee, issued by the Government in the early part of this year. The subject is not new, and since the striking address of Dr. Ferranti in 1910, many reports by Committees and experts have been made public.

In 1918, a committee appointed by the Board of Trade, under the chairmanship of Sir Archibald Williamson, issued a report in which they recommended the division of the country into districts for the purpose of electricity supply, and the concentration of generation in a comparatively small number of large stations equipped with modern plant and favourably situated for cheap coal and adequate water supplies. It was proposed that Joint Electricity Boards composed of members representing the existing supply authorities, and certain other members elected to represent the manufacturing and railway interests, should take over the existing stations and transmission lines in their respective districts, and construct new stations and transmission lines as required. The Report was followed by the Electricity (Supply) Act introduced by the Government in 1919, to carry out the main recommendations of the Report. This Act also set up a body of Electricity Commissioners, to promote, regulate, and control the supply of electricity in the country, and provided for the setting up of Joint Electricity Boards as recommended by the Report. The Bill, as it left the House of Commons, contained compulsory provisions with regard to the acquisition of stations and transmission lines, which were afterwards deleted in the House of Lords, with an understanding that they would be incorporated in a new Bill during the following session. This understanding was not fulfilled, with the result that it has been left to voluntary co-operation amongst the local authorities to set the machinery of the 1919 Act in operation. Schemes have been prepared and inquiries held by the Commissioners in most of the districts into which the country was provisionally de-limited, but the progress made has been by no means proportionate to the time and expense involved. A certain amount of co-operation has taken place, but generally speaking it has been found that the authorities were unwilling to transfer the ownership and control of their stations to another authority or to incur financial obligations for works outside their own district. Instead of Joint Electricity Authorities, so-called "Advisory Boards" were set up to advise the Commissioners regarding district developments. It may be confidently said that the work of these Boards has been largely superfluous, and the extensions which have been made during the last five years would have been carried out had there been no Boards in existence. The failure to achieve co-ordination amongst existing authorities has served to emphasise the necessity for additional powers, and the present Government, shortly after coming into office, appointed a committee under the chairmanship of Lord Weir, to review the whole position and to make recommendations as to the measures which should be adopted. The Committee submitted the report to the Government in May 1925, and the proposals contained in the report have, with certain modifications, been incorporated in the Electricity Bill, 1926, which has passed its second reading and is to be reported to the House, after a searching and exhaustive examination by a standing committee. It appears that the Bill—with probably some minor alterations—will become law before the end of the year. Before examining the proposals in the Bill, it is necessary to refer briefly to the present position both as to generation and transmission.

Generation

The electrical supply industry in this country dates back to 1883, when the first Electric Lighting Act was passed, enabling local authorities and private companies to obtain powers to supply electricity in certain specified areas. These areas, coinciding in most instances with local Government boundaries, were necessarily small. The means for generation and transmission of high voltages had not arrived, and the voltage of supply was generally limited to the pressure suitable for incandescent glow lamps which at that time did not exceed 110 or 120 volts. Within the next 15 or 20 years, hundreds of small generating stations, with restricted areas of supply and with different systems and pressures, sprang up all over the country. Under the conditions then existing, it was perhaps inevitable that different systems should be adopted, but the unfortunate result has been that we have at the present time some 572 authorised

undertakings, with powers to supply electricity, owning 438 generating stations. There are, in addition, about 103 stations owned by railway companies, tramway authorities, and non-authorised undertakers, which brings the total up to 541. The want of co-ordination had led to the adoption of different systems of supply, and in London alone there are 70 generating stations, with 50 different systems and 20 different supply pressures.

The average cost of supply for all purposes for the year 1923 was 2·17d. per unit, and the consumption of electricity from the public supply stations 110 units per head. In view of the comparisons which have been made between the consumption of electricity per head in this country and in other countries, it should in fairness be pointed out that the conditions are widely different. In this country we had for many years a cheap supply of good quality coal, widely distributed, and in close proximity to the industrial areas. During the development period between 1895 and 1912, small coal suitable for steam raising, could be purchased in most industrial districts for 7s. to 9s. per ton delivered. At these prices it was hardly possible in many districts to make out a case for the purchase of electricity if the latter had to bear heavy transmission costs. It was cheaper, indeed, to convey coal to the factory than to convey electricity. On the other hand, in those countries where electricity supply showed rapid development, like Norway, Sweden, Denmark, Switzerland, and Italy, coal was scarce and dear, and even France, Belgium, and Germany were unable to supply their own requirements and imported considerable quantities of coal from this country. Because of our cheap coal, we had the cheapest gas in the world, and this for many years was a formidable competitor to electricity supply. There are other reasons, such as the employment of water power, which is a comparatively negligible quantity in this country. Certain other countries use large amounts of electricity for special purposes like irrigation of the land and for processes special to themselves. This naturally increases the units consumed per head of the population.

The possibility of centralising the production of electricity on a large scale is really due to the invention and development of the steam turbine, a British production which we owe to the genius and skill of a British inventor, Sir Charles Parsons. Starting with small generating units of 200 or 300 h.p., and progressing through stages of 5,000, 10,000, and 15,000 kilowatts, it is now the practice in large stations to install sets of 40,000 or 50,000 kilowatts or more, and one set recently ordered by an American Supply Co. is said to have a capacity of no less than 130,000 kilowatts. With increasing size, there has been a corresponding development in design with improved efficiency, so that the turbo-generator in large units is now beyond question the ideal prime mover for the production of cheap electricity. The improvement in central station equipment has extended to the steam raising and auxiliary plant, and the modern power station with mechanical handling of coal and ashes, with high steam pressures and superheat, and with every device installed to ensure efficiency and economy, shows a degree of progress which is probably without parallel in any other industry.

Transmission

Under the conditions obtaining in this country, the transmission of electricity has not kept pace with its generation. This is due to the compact nature of the areas supplied and to the prejudice against overhead transmission in any but sparsely populated areas. A considerable amount of underground cable for pressures of 22,000 and 33,000 volts has been laid, but there are problems in connection with the manufacture of these high tension cables which have not been entirely solved. The cost of underground transmission is comparatively high, being at least twice the cost of overhead transmission, and for reasons already indicated it has been found more economical to generate electricity locally than to transmit over distances of more than a few miles. Our backwardness in this respect is very striking to anyone who has visited the Continent in recent years

and seen the countryside covered with steel towers and high-pressure lines, carried in many cases through populous districts and tapped to supply secondary lines—also overhead—for furnishing supplies *en route*.

Turning now to the proposals in the Weir Report Scheme, it is proposed—

(*a*) To create a new body to be called the "Central Electricity Board" with administrative and financial powers to carry out the provisions of the scheme.

(*b*) To close down 432 existing generating stations and to produce the whole of the energy required in the country in 58 selected main and secondary stations, of which 43 are existing and 15 are new.

(*c*) To construct a "grid-iron" of high tension transmission mains interconnecting the selected stations and coupling up with existing regional transmission systems and the other existing stations. A sum of £25,000,000 will be required for the first section of the "grid-iron," which is to be constructed during the first five years.

(*d*) That all energy generated at selected stations is to be purchased by the Board. This energy to be resold to the owning authority of the selected stations at cost price plus administration charges to the full extent of the local requirements of the aforesaid owning authority, and the balance will be sold by the Board to authorised undertakers for distribution in their respective areas.

(*e*) That the new stations required, and extensions to existing stations are to be constructed by existing owners, the capital to be raised under Government guarantees as to principal and interest. If the owners are not prepared to carry out such extensions the Board will make the extensions themselves. The owners of selected stations are to operate them in accordance with directions of the Board and in the case of dispute the Board may acquire the station themselves at a price determined by a schedule in the Act.

The total expenditure estimated for the whole scheme is £250,000,000 of which it is estimated that one half will be required to develop distribution schemes and will be raised by the local authorities or the companies who own and operate these systems.

The experts who framed the technical estimates assumed that the generating costs in selected stations will amount to not more than ·31d. per unit, and main transmission costs to ·03d., making a total of ·34d. per unit for high tension energy delivered for distribution. The average cost for distribution for all purposes, lighting, power, &c., is taken at ·5d., making a total cost of ·84d. per unit. Making allowance for administrative charges, it is estimated that the average selling price over the country will be reduced from the present figure of 2·17d. per unit to 1d. per unit or less. As a result, it is anticipated that the consumption of electricity will increase from 110 units per head to 500 units per head, or an increase in the total consumption from 4,000 million units to 20,000 million units per annum.

The scheme is certainly not lacking in boldness of conception or breadth of vision, and if realised, will bring us to the "electrical age" visualised by Dr. Ferranti sixteen years ago. It has aroused criticism in many quarters, including existing supply interests. The benefits—if anticipations are realised—are readily granted, but the estimates of results have been questioned, and the financial and administrative proposals have aroused strong opposition.

Turning to the estimates, the generating cost of ·31d. per unit is certainly much lower than the average cost to-day, but is very little lower than the corresponding costs in several modern stations in this country. The improvement in generating efficiency during the last few years is hardly realised by the general public. As an example, I take the South East Lancashire district, which is fairly typical of industrial districts in the country. In 1919-20 the average coal consumption of the whole of the electrical undertakings was approximately 3·1 lb. per unit generated. In 1923 it had fallen to about 2·2 lb. per unit, and for the year ended March last it was approximately 1·9 lb. This is for the whole

of the stations, good, bad, and indifferent. In the larger stations the consumption is as low as 1·6 lb. per unit. The total working costs in these large stations to-day is not more than ·2d. per unit, and in some cases less. Assuming the construction costs of new stations to be not more than present-day prices, and having regard to the lower capital charges as a result of Government guarantees, the total estimated cost of ·31d. per unit is, I am sure, a realisable figure under the conditions set out in the scheme. With regard to the cost of transmission, the figure of ·03d. per unit must obviously be to some extent speculative and the actual cost cannot be ascertained until the nature and extent of the transmission lines has been definitely decided. The cost of ·03d. per unit to cover capital charges and transmission losses appears on the low side, but even if the amount is increased by 25 per cent. it will not substantially affect the total cost of energy delivered to the consumer. It may be assumed that the cost is based on overhead transmission at pressures of 66,000 and 132,000 volts.

Accepting the estimates of generation and transmission in the report and assuming the "grid-iron" constructed delivering high tension energy at approximately ·4d. per unit, there still remains the question of energy consumption, estimated in the report to be 500 units per head in 1940. The success of the scheme depends entirely on the estimated increase being obtained, and if this estimate is not realised the "grid-iron" may become a burden instead of a help to the supply industry. It is estimated that in addition to the average consumption of 110 units per head from public supply, there is a further consumption of electricity from private industrial plants and small generating stations, which it is estimated would bring up the present total consumption to 200 units per head. The electricity now produced in this way would no doubt in nearly all cases be taken from the national "grid" when supply is available. There still remains a balance of 300 units per head to be obtained from other sources. What are the sources available ? There is at present a rapid growth in the use of electricity for lighting and for domestic purposes, which is certain to be accelerated under the scheme, but this is hardly likely to account for more than an increase of 50 units per head. The electrification of railways would, of course, provide a substantial and remunerative load, but for some reason railway electrification in this country, except for London suburban traffic, has made very little headway, and we compare most unfavourably in this respect with America and Continental countries. It has been demonstrated by experts whose authority is unquestioned, that electrical operation of the railways, with its many advantages, would cost no more than the present system. The slow progress of railway electrification is to some extent due to differences of opinion as to the choice of the system to be employed. In the meantime, at any rate, the railway demand cannot be considered an important factor in the realisation of the Weir scheme. There remains, then, the growth of the demand for electricity for industrial purposes.

In many industries the advantages of electric driving are so great that it has been brought into fairly general use, although the cost of electricity has been comparatively high. These industries comprise shipbuilding, general engineering of all kinds, and many others. It may be interesting to note that there are a large number of collieries in this country purchasing electricity from supply authorities in preference to generating it themselves. Public supply comes out most favourably where the power using machines are scattered, and the demand is intermittent. There are industries, however, where progress in adopting electricity has been comparatively slow. In these cases a large amount of steam is required for process work. This steam must be raised in any case, and the additional steam necessary to drive the mill engine or turbine has been looked upon as a kind of by-product, which costs nothing except the additional coal consumed by the boiler fire. The most conspicuous example of these conditions is the textile industry, and it is not surprising that manufacturers in this industry have been slower to realise the advantages of public supply than in other industries requiring similar amounts of power. Another reason is that textile mills as at present

constructed appear to have been designed for central driving, and the power can be transmitted from the engine to the point where it is required with the minimum of shafting and intermediate gear. In the early days of electricity supply, the supply authorities did not even consider it possible to quote prices which would compete with local power production in textile mills, and the location of the central electricity station and its equipment, while suitable for local traction and lighting requirements, did not permit of economical extension on a scale sufficient to supply the textile load. The position changed during the war, owing to increased prices of fuel and labour, and some activity on the part of a number of supply authorities in modernising their stations by installing larger and more economical generating plant. The prices for public supply for textile driving during recent years have varied in Lancashire from about ·55d. per unit to ·8d., the average price being about ·65d. At this price, a number of mills have found it remunerative to change over to public supply, and in all cases, I believe, the results have been entirely satisfactory. In practically all these cases electricity has been adopted to supersede existing power plant, and in this respect is at a disadvantage when comparisons of cost are made. In the case of new mills, with a public supply available at the prices indicated, there would be no question as to the most economical method to adopt. A retarding feature has been the introduction in textile mills of small turbines of 300 to 500 h.p., which can be either used for complete mechanical or electrical drive or a combination of both. These turbines are generally designed for "steam bleeding," the steam being taken off the turbine at suitable pressures for process work. Under suitable conditions the thermal efficiency is comparatively high. In a recent case where the power requirements accounted for 60% of the total volume of steam to be raised, and process requirements for the remaining 40%, it was estimated that public supply would require to be given at not more than ·45d. per unit to compete with local generation. This was probably an exceptional case, and the general opinion appears to be that if electricity can be delivered as low tension energy at a price between ·5d. and ·6d. per unit, it will be generally adopted for textile purposes. Incidentally, it may be said that electricity could be employed with advantage for a good deal of the process work for which steam is now considered necessary, the only question being that of the cost of supply.

The outstanding advantage of electricity as a motive power in the textile industry, is the fine steady drive on the machinery, and in numerous cases where it has been adopted the result has been increased output and a better product. Steadiness in the drive is obtained in the highest degree when each textile machine is driven individually by its own electric motor but can also be quite satisfactorily constant when a motor drives a group of machines in its immediate neighbourhood. When the transmissions by rope or belt and line shafting become lengthy, cyclical irregularities are frequently set up which become more pronounced as the transmission grows longer, and if the power is supplied by a reciprocating engine, these irregularities—existing as they do in no small degree in the very source of the power, are exaggerated at each stage of the transmission and become a serious factor in limiting output. It is impossible in the limits of this paper to go into much detail regarding the employment of electric power in the textile industry, but I would like to emphasise the danger of generalising from isolated experience. It is important also to remember that while very little, if any, increase can be expected in the efficiency of private power plants, the effect of co-ordinating electricity supplies on the lines of the Weir Report is bound greatly to improve the efficiency of public supplies and so reduce the cost.

It is impossible to generalise where there are so many variable factors to consider, and local conditions must necessarily decide between public supply and private generation in most cases. In making a comparison, however, all the factors should be taken into account. In the case of an existing private installation, the capital has already been spent on the power plant, and interest charges do not enter into consideration, but an allowance should be made for

depreciation. The value of the buildings and the ground occupied should also be considered if these could be used for production purposes. Rates and taxes, water, and other items of cost should be included, and although it is not usual to debit any proportion of management charges against power costs, the indirect benefit of relieving the management of the responsibility of operating a power installation should not be overlooked.

The question of spare or standby plant does not arise in the case of the usual mill engine, which is probably the most reliable type of prime mover in existence, but in the case of steam turbines the same measure of reliability cannot be claimed, and in view of the serious loss which would result from a total shut-down due to a breakdown of the turbine or its auxiliaries, it is desirable to have spare plant available, or at least to divide the power production between two or more units.

There are undoubted advantages in having what is practically an unlimited supply of power, which may have no direct effect on the power costs but which have a beneficial effect on the operating conditions of the mill. When all considerations are taken into account, the only limits to the use of electricity for textile purposes have been fixed by commercial considerations. To what extent will this limit be altered by the national scheme ? The estimated average selling price of 1d. per unit as a result of the scheme is, of course, for all classes of supply, and includes distribution costs amounting to over 50% of the total price. These distribution costs are chiefly incurred for lighting and small power supplies, and it is usual to fix a price for large power supplies considerably below the rates charged for lighting. Assuming the same ratio is maintained for energy supplied from the national "grid," it is probable that the price for lighting purposes will be from 2d. to 3d. per unit, while the price for power supplies may vary according to load factor from ·35d. to ·6d. per unit. The average price for power should certainly not be more than ·45d. per unit. It will be granted, I think, that under these conditions the commercial limitation which exists to-day is of a temporary nature only and will disappear when the national scheme comes into operation.

The other important limitation to a national scheme is the existence of a number of medium-sized stations which are favourably situated for coal supplies, and have natural condensing facilities for a limited output. There are a certain number of these stations in the textile districts, where coal supplies are well distributed, situated near canals, from which condensing water can be drawn sufficient for loads of 15,000 or even 20,000 kilowatts. These stations have been modernised and the old plant supreseded with modern turbo-generators of 3,000 and 5,000 kilowatts capacity each. The original capital expenditure has been almost, and in some cases entirely liquidated, so that there is only the "running charge," and the capital charges on the modern plant to be considered. In a number of these stations it will be difficult to make out a case for purchased energy from the "grid-iron" if heavy charges have to be incurred for local transmission lines, transformers, and switchgear. It would appear that a number of these stations will continue to operate, although not included in the list of "selected stations."

It is not the intention of this paper to comment on the administrative provisions of the Electricity Bill. A considerable amount of criticism has been directed to the proposed arrangement between the owners of selected stations and the Central Board. The separation of ownership from control,it is sitated, will lead to difficulties in operation and provides no incentive to initiative or efficiency. It is also pointed out that the geographical situation of the smaller power stations is such that a bulk supply could not be furnished except at a loss, which must fall on the users of electricity in the larger towns. Much of this criticism may be justified, but so far there are no alternative schemes put forward which could claim to fulfil the objects aimed at.

In the only practical alternative which I have heard put forward it is proposed to combine the generation of electricity with the manufacture of gas and certain by-products by a low temperature carbonisation process. It is pointed out that the industries of the country have grown up around the coal producing districts, and that a scheme for generating at the pithead—meaning from a group of closely-situated collieries—would obviate the necessity for an expensive "grid-iron." A reference to a map of the coalfields of Britain will show that this is true at least for the chief industrial districts. The chief item in the generating cost is still fuel, which in a modern super-station accounts for 60% to 70% of the total generating cost. Proposals of this kind have been brought forward from time to time, but hitherto it has not been possible to show commercial results, due to the difficulty of disposing of the by-products at remunerative prices. The chief of these by-products is coke, and so far it has not been possible to produce a coke which is suitable either for domestic use or for raising steam in a boiler furnace. It is claimed that the difficulty with regard to the latter has been overcome by the introduction of pulverising methods, which enables the coke to be burned as a fine dust is a specially constructed furnace. It is also pointed out that there is generally a large percentage of low-grade fuel produced from the coal mines which is not worth the cost of transport if a market has to be found more than a few miles away. This fuel in pulverised condition could be mixed with pulverised coke and employed to raise steam for driving turbo-generators. Natural condensing facilities would probably be absent, but it is claimed that cooling towers at a comparatively low capital cost could be employed, and that the loss in efficiency as compared with river water (which frequently involves heavy expense in constructional work) is not more than 8 per cent. This difference, it is said, would be more than neutralised by the reduced cost of fuel. A further possibility in connection with the pre-treatment of coal is the production of oil fuel, which is now extensively used in the Navy and Mercantile Marine.

The question of low-temperature carbonisation receives only a brief reference in the Weir Report, but it is inferred that any power which can be economically generated in conjunction with low-temperature carbonisation, would be delivered to the "grid," thus finding a ready market. It must be remembered that the Weir scheme only lays down the general lines of development, and that detailed schemes have yet to be prepared and submitted for the various districts. The most that can be said is that before any system is stereotyped for the whole country, further inquiry should be made in any direction which will not only produce cheap electricity but conserve the greatest and most important of our national resources.

The only other alternative—if it can be called one—is to leave things as they are and allow what is called "natural development" to go on. It is pointed out that a number of small stations have been voluntarily closed down in favour of bulk supplies, and that the process of concentrating generation should be gradual and not forced beyond its natural and economic rate. Those who put forward this contention are obviously overlooking the experience of the last five years. When the compulsory clauses were deleted from the Electricity Bill of 1919, it was confidently asserted that voluntary co-operation would take place and that the objects of the Bill could be achieved without introducing elements of compulsion. The contrary has been the case, and the causes which rendered co-operation impossible still exist. In this connection one has to remember the different type of authorities who are at present entrusted with public electricity supply. There are some 335 local authorities and 237 companies, including 28 power companies, with statutory rights of supply. The companies, other than the power companies, are nearly all purchasable at specified dates by the local authorities, but the power companies hold their rights in perpetuity. The chief obstacle to co-ordination has been the unwillingness of local authorities to take bulk supplies from the power companies, as an alternative to extending their own stations or constructing new stations. These

authorities contend that the security of the public rates enables them to borrow capital at 2% to 3% lower than the rates of interest paid to the companies' shareholders, and even where technical conditions may be favourable, they strongly object to handing over the generation of electricity, which they regard as a public utility, to a company whose primary object is naturally to make profit for its shareholders. The question of municipal versus private ownership of public utilities is outside the scope of this paper, but it is necessary to state that the existence of these two types of authorities, operating individual systems which ought, in the interests of the district and the nation, to be under centralised control, has been a serious hindrance to co-ordinated development. The Weir scheme is the first real attempt to overcome this difficulty. Under the scheme, the Board will itself buy all the energy from selected stations, both municipal and company owned, at a price which includes and limits the profits to be charged by the companies. This energy will be sold direct to the distributing authorities, and provision is made so that the benefit of cheap generation will be passed on to the consumer.

A legitimate fear is being expressed that the scheme is too big to be carried out and operated by one central authority. It must be remembered, however, that the Bill re-enacts the provisions of the 1919 Act regarding joint authorities, with the important difference that instead of the authorities interested putting forward a scheme the Commissioners themselves will formulate schemes which will include provision for carrying out works for the development of supply within the various districts. It would appear that the simplest way to carry out the Weir scheme will be for joint electricity authorities to be set up over districts which will probably be larger than was contemplated under the 1919 Act, and that a scheme for each district, including new stations and transmission lines, should be carried through under the supervision of the Central Electricity Board. As the districts become gradually reorganised, they will probably interconnect with each other, so leading up to the complete national scheme. The provision made in the Bill for financing the new stations and the construction of transmission lines would apply to the district schemes, provided, as would be the case, the district scheme conforms to the national scheme.

The subject is one of great national and industrial importance. The demand for electricity which will arise when trade conditions improve will call for an immediate and adequate source. With hardly an exception, it is agreed that the method of leaving the supply of what is now a national necessity to individual owners of supply systems, who are bound by circumstances to take a narrow and local view, cannot be continued if this country is to regain its former position in the world of industry and commerce. The Weir scheme is no doubt open to criticism, but it is at least a bold and comprehensive effort to deal with a problem of great complexity and pressing urgency. The expenditure on the scheme may seem large, but it is probably less than would be incurred if individual development were allowed to proceed. It is no use at this time of day to condemn legislative interference with the natural development of an industry. A cheap supply of electricity is a national question. It has been and must continue under statutory authority. It is closely related to questions of transport, housing, and the conservation of fuel. Existing methods having failed, it is the nation's duty to take what steps may be necessary to achieve the object on which all parties are agreed. If all those interested will take a broad view and look at the question apart from existing interests and local sentiment, with full regard to the future growth and prosperity of the country, they will co-operate and assist to carry out a scheme which, if realised, will prove of incalculable benefit to the nation.

Discussion

Mr. J. K. Kerfoot (Sidcup) thought it would be interesting for the members of the Institute to be informed as to the progress of the Municipal Electrical Station in Shanghai. He understood that Mr. Robertson had all the details of

the installation. When he, the speaker, was out there in 1913, the engines and boilers of his mills were already over-loaded, and he approached the Municipal Council with a view to obtaining a power supply. Up to that time the municipality had not catered for power purposes, but had devoted their attention to supplying the lighting demand of Shanghai. By the installation of five motors it was found possible to start up 10,000 spindles and preparation machinery, and from that period the electrical installation at Shanghai had become one of the largest power generating plants in the world. All this progress had been made in thirteen years. The question might quite reasonably be asked as to how all this arose. In 1920 there was a very big boom in cotton mill construction in Shanghai, and the Chinese thought it would be cheaper for them to obtain their current from the municipal authorities. Therefore, all new mills were installed with electrical driving, and there were now power plant units of 25,000 kw. in the central generating station. Nowadays, all the cotton mills, silk mills, and rice mills were supplied with electrical power. It was quite possible that some benefit would thereby accrue to Lancashire, because the engines and boilers in the old mills were obsolete and there was a general tendency to install the electrical power drive. The same practice could, with advantage, be adopted in the case of a great many Lancashire mills. Wherever a power plant was consuming more than 2 lb. per horse power per hour, and current could be supplied at a cost of approximately 0·5d. per unit, the plant should be scrapped. Being the first one to apply to the Shanghai Municipal Council for a power supply, he obtained considerable concessions from the Council, who had used his mills for advertising purposes. The engines in the old mills had been running for 23 years night and day, and, quite naturally, the boilers were past their prime. More steam was required for bleaching and dyeing, so he reduced the steam pressure on the boilers and converted all his weaving—5,000 looms—to electrical group driving, and the scutching-room machinery was driven by individual motors. His experience led him to believe that, with the exception of the scutching-room and for bleaching and dyeing machinery, group driving was to be preferred for ring frames, mules, and preparation machinery. He endorsed the opinion expressed by Mr. Robertson, that the time had arrived when Lancashire manufacturers would have closely to examine the cost of their power. If Lancashire and Yorkshire manufactures could be developed upon the lines of centralised electricity production, then the right course to adopt would be to drive the mills electrically. He had no hesitation in saying that the production throughout the mills, both as regards quantity and quality, was superior with the electrical drive. At the same time, it must not be overlooked that the great success which had been made of the Shanghai Municipal Electrical Station had been brought about by the constant power-load required by the mills—24 hours per day and six days to the week the year round. Although the station had to supply lighting for over 1,000,000 inhabitants, the engineer had informed him that it hardly counted in their cost of running the installation. The coal used was imported from Japan and of a poor quality, only containing about 6,200 calories and costing about 20s. per ton. Even in this country, with a much better quality of coal, say at 16s. per ton, the success of the large electrical stations and their ability to supply current inside the 0·5d. per unit, would depend very much on a large constant power-load during ten hours per day and a large increase in the consumption of current for domestic purposes.

Mr. G. Clapperton (Atherton) said he was connected with a firm which had an electrical plant, and he was informed that it would be doing the firm a good service to take out the motors and put the old engine back. He had noticed that since the scheme was mooted there had been a considerable number of police court prosecutions in regard to atmospheric pollution. Apparently, if electrical power plants were not installed from choice they would very soon have to be from compulsion.

The Chairman said that the three main items of expenditure in a cotton spinning mill were (1) the Cotton, (2) Wages, and (3) the Power. Dealing with the power, coal at 16s. per ton showed an advantage over electrical energy at anything like 0·45d. per unit, and thus turned the scale in favour of mechanical power. This was the main reason why progress had not been made in Lancashire in regard to the electrical drive. The cotton trade worked to very narrow margins, and there was a very small difference between loss and profit. For years past some of them had had mills fully equipped with electrical driving, and had been in a position to compare costs. At 0·45d., when coal was at 16s. per ton, the mechanical drive was greatly to the benefit of the mill as compared with the electrical drive. There was a steady, regular usage of power from the time when the mill started on the Monday morning until the Saturday noon. It was a standardised power, and the engines and boilers were fitted to meet the needs of the weight of the undertaking. It was necessary to be very careful in connection with the adoption of such a scheme as that described by Mr. Robertson, as it would be quite easy to injure industries very materially. The scheme outlined was unquestionably a magnificent one and, from the standpoint of the country, might have many advantages. Those who had had the privilege of visiting Sweden, Germany, and Switzerland, would know that every farm house, however remote from a town it might be, was lit electrically, and also that many appliances were driven electrically. It must not be lost sight of, however, that the reason was that coal was dear in those countries, and that a general supply of electrical energy was part of the national programme for other purposes and for other ends. He had no objection himself to the adoption of such a national programme for this country, but he had a very great objection to setting up a Board, say in London, which would attempt to deal with the great industries of the country they knew nothing whatever about. He also felt a great amount of diffidence in agreeing that there should be built up a common system of prices. In the latest amendments to the Bill, some variations were to be permitted and the standard was to be based upon the price paid for coal at the present time. They were all looking forward to a great development of electrical enterprise in the next few years in the big centres of industry, the interests of which must be sufficiently protected from contribution to the cost in respect of more remote districts. It appeared certain that small outlying townships, villages, and farm houses, &c., would be subsidised under the Bill at the expense of the great industries of the country. It was a feature which did not appear upon the surface, and one had to read the Bill very carefully to realise it. If the great industries could be placed upon a plane equivalent to that they would be on if they installed big batteries of their own—because they could beat anything which had been shown in the Bill in connection with costs—then those industries would back up the Government whatever their scheme might be, and work for a national plan. The cotton industries would have to be fully assured on that head, and proposals would have to be properly introduced. Words or promises could not be accepted; an Act of Parliament would be absolutely necessary. Otherwise there would be a fight against the Bill, and an endeavour to limit its operation in every way until such safeguards were introduced. The controlling heads of the large industries did not all work on one plane of thought. A supply of electrical energy for power purposes was very convenient for the heavy iron industries, which required a big peak of power brought in at a given moment, and which did not wish to install immense engine power in order to meet that peak. It might be of greater advantage for them at the time when they were using electrical energy, to pay a very high figure for their current. It was quite another matter where there was constant steady usage week in and week out. Where there was a maximum and steady use differential treatment had to be provided.

Mr. J. S. Peck (Manchester) felt that the lecturer had given a very fair synopsis of the new Electricity Bill. He judged that Mr. Robertson did not consider the Bill to be perfect, with which view he agreed; nevertheless he thought it was better to have a measure which, although it might contain minor defects, had compulsion behind it than to leave the industry to continue in its present state of confusion. As usual, on the introduction of a new Bill, vested interests which might be, or which imagined they might be, adversely affected, offered serious criticism, much of which was probably unjustified. Many who had criticised this Bill had evidently never taken the trouble to study it closely and to understand its details. It would appear that every effort had been made to safeguard the interests of those already engaged in electrical supply; the special precautions taken to safeguard vested interests could be demonstrated by citing one particular provision—"If the limb of a tree interferes with the distribution network the owner of the tree will be notified to lop the limb within twenty-one days. If he objects, he may appeal to the Ministry of Transport, who causes an inquiry to be held. If the decision is against the owner of the tree he is notified that he must lop the limb, and if he fails to do so within a reasonable time the Board may cause the limb to be removed." Safeguard could scarcely be carried further. The lecturer, said Mr. Peck, has pointed out that as far as efficient generation of electrical energy is concerned, this country is abreast of any other; there are generating stations in Great Britain which, considering the conditions under which they operate, are giving results equal to, if not better than, those obtained in any other generating stations in the world. When it came to the question of distributing large amounts of energy over long distances at very high voltages, our experience was limited. There was something more in overhead transmission than the erection of towers and the stringing of wires on insulators. A comprehensive study, he thought, of the whole scheme of inter-linking and distribution should be made at once in a thoroughly scientific manner and in consultation with engineers who had had the greatest experience in connection with high-tension distribution systems. Such a course would undoubtedly save unnecessary expense later. The ultimate object of the new Bill was to make it possible to supply electricity at a minimum cost and to make it available to the maximum number of consumers. The Bill could, therefore, only succeed if supported by the community; the greater the support the cheaper the supply. While electrification of textile undertakings was increasing, there was still an enormous field to be developed. It was often difficult to demonstrate to a mill owner that his electricity bill of the future would be less than his coal bill of the past. The advantages of electrical drive had to be shown to lie along other lines. The value of these particular advantages was often difficult to assess, but the fact remained that those who had installed electric drive are, in general, satisfied as to the financial aspect. Not many years ago it was necessary to plead with a man who was equipping a machine shop to install electric drive, but to-day the builder of a machine shop would consider nothing else. He felt that before many years such conditions would obtain in the textile industry, and electric drive would be as universal in the textile mill as it now is in the machine shop.

Mr. John Crompton proposed that a very hearty vote of thanks be accorded to Mr. J. A. Robertson for his valuable address.

Mr. R. H. Friend (Manchester) thought that Lancashire mill owners had not taken so much to electrical driving during recent years, chiefly owing to the state of trade, and, secondly, owing to the cost of electrical power, which was certainly on the high side at present. But he thought they would all agree that the cost of power was a very small percentage of the cost of production. In fact, it represented a figure of only $1\frac{1}{2}$ to 4%. The lecturer had stated in the paper that the majority of textile mills were laid out for engine drive. This was certainly the case with most of the mills that he had visited in this country.

Generally speaking, a saving of power could be shown by electrification even in the mills laid out for engine drive, and it was always a good policy not to have all one's eggs in one basket. An article on the Electricity Bill, in a recent issue of the *Observer*, referred to comments in the German Press regarding the Bill. The article read as follows—"The carrying through of this great electrical scheme by England will considerably influence the future progress of German industry and, above all, German exports of industrial products upon the world market. We shall have a much more difficult fight on the world market owing to increased difficulties of industrial export and the progress created by the cheap cost of *production in English industry." He had much pleasure in seconding the vote* of thanks to Mr. Robertson for his interesting address.

Mr. Robertson, in replying to the discussion, said Mr. Kerfoot's experience with electricity supply at Shanghai was extremely interesting and was a good example of what could be done with electricity where the field was entirely new. He quite agreed that 2 lb. of coal per horse power was a good result. In his business he sometimes examined records of power costs and he found the results were generally expressed in indicated horse power. A consumption of 2 lb. per indicated horse power meant approximately 2·2 lb. per shaft horse power. Comparing this consumption with power station results, a consumption of 1·6 lb. per kilowatt at a power station was equivalent to 1·2 lb. per electrical horse power, so that the fuel consumption at a central power station for a given amount of power was slightly more than half what it cost in a mill. Another speaker referred to a price of ·83d. per unit, and he quite agreed that for textile purposes this figure was not a commercial proposition. If the price was paid in a Lancashire town, then it was considerably above the average price and would no doubt be reduced, because Lancashire was well ahead of the rest of the country in regard to cheap supplies. Regarding prosecutions for smoke nuisance, the mill owners had a duty as well as other manufacturers, and if they could, without serious financial loss, assist to abolish the horrible smoke pall which hung over most Lancashire towns, the expenditure involved would be a good investment. He frankly admitted that it was difficult for an impartial outsider to make accurate comparisons between the cost of private power production and public electricity supply. The President had stated that ·45d. per unit did not compare favourably with the cost of producing an equivalent amount of power by private plant. On the other hand, he knew a large manufacturer in Lancashire who began to electrify his mills about four years ago. He was very doubtful and hesitated over the matter for some time before he would agree to pay ·65d. per unit for low-tension energy. This price was offered with a basic coal price of 16s. per ton, with a variation in price corresponding to the actual cost per unit at the power station. This manufacturer was thoroughly satisfied with the results, and has since electrified several additional mills. This experience could not be ignored. There were, of course, always differences in management, &c., which might vary the power costs, and there were also different methods of calculating the total cost of power production at private installations. The President's reference to the provisions of the Bill which would result in a cheap supply of electricity for the villages and countryside at the expense of large towns was quite legitimate criticism. It should be remembered, however, that the Bill only provided the machinery for a national supply, and the operation of the machinery was to be entrusted to a Board of eight experts. It was not likely that these experts, some of whom at least would be commercial men, would expend large sums of money in supplying farms and wayside cottages if, by so doing, the price of electricity would be increased to larger industrial consumers. After all, there was nothing in the Bill which compelled a manufacturer to take a supply of current. If he so desired he would still be able to generate power from a private plant. The success of the National scheme depended upon the Board so adjusting the prices for the different classes of

supply as to obtain an enormous increase in the existing output of electricity. If the supply to country districts could only be given at a loss, then he agreed that it would be wrong for the industries of the country to bear it. It should be remembered, however, that one of the main factors in cheapening electricity supply was the variety in the demand from different classes of consumers. By combining the demand for industry with the lighting demand and the demand for traction, we obtained a diversity factor which appreciably reduced the cost of supply. The agricultural load would, as a rule, tend to improve this diversity factor.

Mr. John Crompton, Chairman of the Council, then took the chair and asked Mr. Percy Bean to read his contribution.

THE SIZING OF ARTIFICIAL SILK YARNS AND A COMPARISON WITH THE SIZING OF COTTON YARNS

By Percy Bean, F.C.S., M.Ph.S.

INTRODUCTION

The success attained in the weaving of single-fold artificial silk warp yarns during the last few years is due, in a great measure, to the improve ents brought about in the machines employed for the purpose of sizing. Just as sizing is essential to the successful weaving of single counts of cotton yarn, so it is essential that the filaments of artificial silk should be bound together by some adhesive substance, in order to strengthen them sufficiently to permit good weaving with a minimum of breakages. Sizing has been the means, undoubtedly, of adapting artificial silk yarns to the manufacture of more extensive varieties and qualities of cloth than formerly, and manufacturers may now use this yarn with confidence, knowing that it is a commercial article from which, in most cases, they can obtain the same loom-efficiency as from cotton. When artificial silk yarns were first used in conjunction with cotton yarns in the production of striped fabrics, the silk employed was usually two-fold, and, on this account, was sufficiently strong to withstand the operations of weaving without the necessity of sizing. It was found, however, that much of the lustre of artificial was lost by doubling, and, in order to obtain the full advantage of this essential characteristic of the new fibre, it was essential to use single yarns spun with as few turns per inch as possible. This of course made sizing essential.

EARLY METHODS OF SIZING ARTIFICIAL SILK YARNS

In the early days of this new industry it was customary in some works to carry out the sizing operations in the hank. A very simple machine was employed, and the hanks were placed on sticks and immersed in the bath of size. The yarn was worked gently for about ten minutes, and then the excess of size was squeezed off by hand. After sizing, the hanks were either taken direct to the hot-air drying stove, or they were placed in cotton bags and strongly hydro-extracted. It was claimed by many firms that they got better sizing when the yarns were first treated in the hydro-extractor, than when they were taken directly to the drying stoves.

Another form of sizing, known as machine, or "bobbin-to-bobbin" sizing, found favour about this time. In this process the yarn was run off from ordinary winders' bobbins through the size contained in a box, and then on to separate bobbins again. These latter bobbins were specially made for the purpose. They were made of aluminium and constructed with the shaft or barrel perforated with a number of holes in order to allow the yarn to dry more easily when they were placed in the stoves. The warps were afterwards prepared from these bobbins in the usual way. The advantages of this system were, that there was very little

tension placed on the wet yarn during the process of sizing, and none at all during the process of drying. This is a very important factor, as will be shown later. Unfortunately the production by this process was small, and therefore not economical except where a few ends only were required to produce the figure of the pattern. Consequently, it has almost gone out of use. It is a matter of interest, however, to know that "bobbin-to-bobbin" sizing is again attracting the attention of engineers, and an attempt is being made to reintroduce it on a larger scale, so as to enable a large number of ends to be dealt with in one run. It will be apparent that the main difficulty will be to construct a machine which will hold from 2,000 to 3,000 bobbins and yet be contained within reasonable dimensions.

PRESENT-DAY REQUIREMENTS AND A MODERN MACHINE

When artificial silk fabrics became more popular the older processes of sizing had to be superseded to meet the requirements of the trade, and machines of the type shown in Figure 1 were invented. These machines differ very considerably from those used in the sizing of ordinary cotton yarns as will be seen by comparison with Figs. 2 and 3. Without giving a full description of the machine at this stage, it will be sufficient to say that it consists essentially of a copper size box, in which revolves a brass roller, and a drying apparatus. The size is picked up from the surface of the roller by this method in sufficient quantity for weaving purposes, and no pressure is exerted on the yarns in the wet state as is customary in the sizing of cotton yarns on the tape frame. In the case of cotton yarns it is important that the size shall be well squeezed into the yarn between the individual fibres, and this can be brought about only by pressure from the squeezing roller, a pressure which would be harmful to artificial silk yarns in the wet state. After picking up the size, the yarn is passed over the drying arrangement. This consists, usually, of two steam-heated plates, or cells, arranged at an angle as shown in the drawing. These cells, which will be dealt with more fully later, are heated by steam, and worked at a pressure of about 25 lb. From the drying cells the yarn is passed to the weaver's beam. In the passage from the size box to the first drying cell there is a slight tendency for the yarn to "twirl," and this is a decided advantage, as will be explained shortly. "Twirling" is more pronounced on the ordinary tape frame or slashing machine, during the sizing of the coloured yarns which go to the borders of dhootie cloths, than it is on this machine. This is due to the longer distance the yarn has to travel from the size box to the drying cylinder, and it is the cause of a good deal of trouble, because the yarns have a tendency to twist or "twirl" round each other when the tape frame is stopped, or when it is running on the slow motion. Much of this trouble is due to the position of the coloured size box, as will be seen from the illustration. It is peculiar that what is the cause of serious trouble in one case has turned out to be a decided advantage in another, because the slight "twirling" in the case of artificial silk yarns allows the size to become twisted between the filaments from the point of contact with the first drying cell and the size box, and so rolls and binds them firmly together from the inside of the thread as well as from the outside. Whilst the distance between the size box and the first drying cell is sufficient to cause a slight "twirling" it is not sufficient to permit the different threads "twirling" round each other as described in the case of the coloured-border cotton yarns on the tape frame. There is no doubt that makers of sizing machines for artificial silk realised the danger of "twirling" if the yarn had to travel any considerable distance between the size box and the drying plate, and also the danger of over-stretching the yarn whilst in the wet state, and they constructed the machines in such a way as to avoid these troubles. It is quite certain that they never constructed a machine intentionally which would give the right amount of "twirling" to produce the beneficial results which have been found in practice. This is one of the happy accidents of which we have so many instances in the history of our manufacturing processes.

COMPARISON WITH THE SIZING OF COTTON YARNS

From what has been said already, it will be evident that the sizing of artificial silk yarns differs entirely from the sizing of cotton yarns. In the former case the sole object is to obtain the maximum amount of strength with the minimum amount of size. In the case of cotton yarns, even in pure sized yarns, a certain feel and appearance is aimed at, even if the goods are intended for bleaching and finishing. The only appearance desirable in artificial silk sizing is the retention of the lustre as much as possible, and, on this account, it is advisable to employ a size as transparent as possible. Experience has shown that thin boiling starches, or partially soluble starches, are more suitable for sizing artificial silk yarns than raw, untreated starches, such as farina, maize, &c. There are many makers of suitably treated starch, but it is not desirable to give names in a lecture of this kind. It may be stated, however, that a starch which will give a similar size to that produced by a mixture of equal parts of white dextrin and ordinary maize or farina may be considered a rough standard. It has been mentioned already that artificial silk yarns require very little size, and experience has shown that a mixing containing half a pound of suitable starch to one gallon of water is strong enough for all practical purposes. The starch should be mixed with water and agitated for a short time. Heat is then applied, and the temperature raised to about 200° F. Gelatinisation takes place, and this completes the process. The size is usually allowed to cool before use, on the machine, and in hank sizing this is a necessity for covenience of handling.

Although the sizing of artificial silk yarns is a very simple process in itself it becomes more complicated, and presents certain peculiar difficulties of its own, when the yarns are intended to be woven into stripes along with cotton yarns. This is partly due to the stretching or elongation of the artificial silk yarns which takes place when they have been wetted and then dried under tension. It has been found that under normal treatment in sizing, the yarn increases about five per cent. in length. This increased length is almost entirely lost if the yarn be again wetted and allowed to dry without being subjected to tension. The effect of this peculiar and characteristic property of artificial silk is important when the woven fabric is subjected to the processes of bleaching and finishing. The cloth is wetted during bleaching, and it is afterwards dried on an ordinary drying machine. During this process no direct tension is placed upon individual threads, and the artificial silk yarn loses much of the elongation which took place when the yarn was sized and dried under tension. If due allowance be not made for this when the artificial silk is sized in the first instance, and further if due allowance be not made by suitably weighting the weaver's beams when weaving, the cloth may come up puckered when it is bleached and finished, or the artificial silk yarns may be broken when the cloth is dried on the drying cylinders. It has been found that viscose silk yarn should be warped about 3% longer than ordinary cotton yarn, for the same length of woven cloth, in order to allow for the less tension which must be placed on the artificial silk beam in the loom than on the one containing cotton yarn, and a further allowance of 5%, as already mentioned, for the elongation of the yarn which takes place when it is wetted out in the sizing operation. Altogether, this is an allowance of about 8% for ordinary plain weaves and rather less for satins.

DETAILED DESCRIPTION OF MACHINE

I am indebted to Messrs. Samuel Walker & Sons Ltd., of Radcliffe, for the detailed drawing of the machine here exhibited. This machine is drawn to scale, and it is interesting in as much it is practically half the size of the actual machine itself. It consists of the following essential parts—

(1) The frame.
(2) The size box with roller or bowl and fittings.
(3) The drying cells or plates.
(4) Glass lifting rods and balancing motion.
(5) Driving motion.

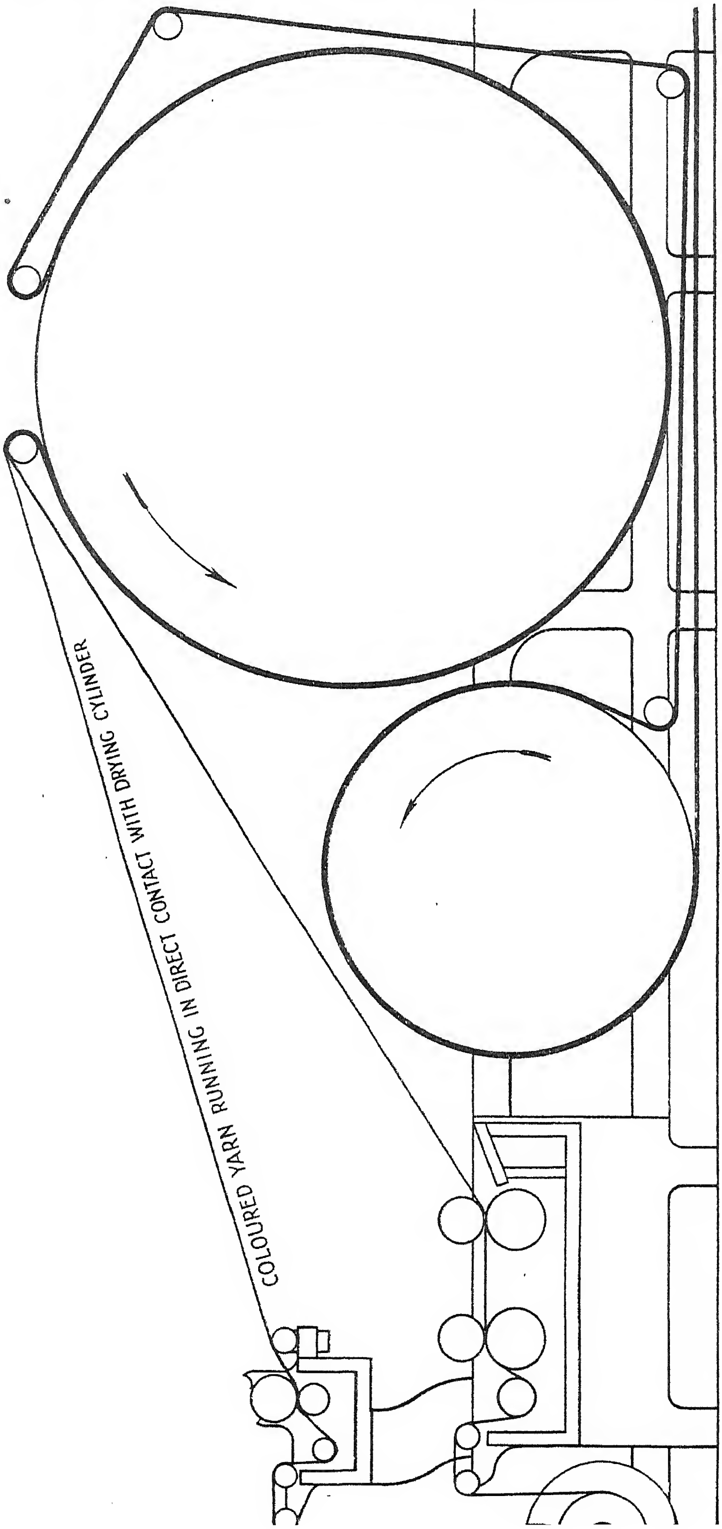

FIG. 3—Tape Sizing Machine showing coloured yarn running in contact with the drying cylinder

The Illustrations from which this block and that for Fig. 2 have been prepared were kindly lent by Messrs. Howard and Bullough Ltd.

The frames are made of cast-iron, and they are securely stayed together by means of wrought-iron bolts and pipes. The top flange of each frame is fitted with four square thread nuts and steel screws for supporting the drying cells, and for adjusting the same to the required angle. The total height of the frames from the floor is about 3 ft. 6 in., and this has been found to be the most convenient height for the average operator. The size box, which is usually constructed of copper, and which is semi-circular in shape, is fitted with an outlet flange at the bottom, to which is attached a let-off pipe and tap. The size roller, which is generally 6 in. in diameter, is made from solid drawn brass tube, and it is usually very heavily electro-plated. This roller, which is mounted on self-aligning bearings, revolves in the size at about 77 revolutions per minute, and in the same direction as the yarn is travelling. In order to adjust the contact between the threads of yarn and the size roller, a copper-tube guide-roller is fitted. This guide-roller which is about 3 in. in diameter, is adjustable by means of screws and suitable slide-bearings.

The drying arrangement consists of two flat chambers, or cells, placed at an angle to each other as shown in the drawing. The first drying cell is inclined upwards from the size box, and this allows the size on the threads to run backwards to the size box, thus assisting in giving a level coating to the thread, and so producing a level yarn which prevents the size "beading" during weaving. The result is there are less breakages of the yarn in the healds and reeds. The second drying cell is inclined downwards, as shown in the drawing. The surfaces of the cells are highly polished, and they should be kept free from grease and dirt. Between the two cells, and also between the reed and the first cell, a glass rod is placed. These rods are connected with lifting mechanism, which may be operated by hand levers from each corner of the machine. The purpose of the glass rods is to raise the yarn completely from the surfaces of the heated drying cells, and from the size roller, when the machine is stopped for any purpose during sizing. It may be as well to mention that the drying cells are usually supplied 77 in. wide on the face. They may be obtained, however, to suit any particular requirement. The cells are made from a special metal alloy, and they are constructed in such a way as to maintain an even temperature over the entire surface. To obtain this result the steam is caused to enter each cell at the highest point, and it is diverted across the inside surface in alternate directions by a series of baffle plates. The condensed water is delivered into a steam trap placed at the lowest end of each cell.

In conclusion I would like to point out that it is important that all sizing machines should be erected in rooms having good solid concrete floors if possible, and the rooms should be lofty, well lighted, and well ventilated.

Discussion

Mr. J. W. W. Shuttleworth (Clitheroe) said that the difficulties of sizing artificial silk were intensified by the fact that it was undesirable to stretch the yarn during the wet process. In starting up certain machines there was a tendency to rolling as the yarn left the sizing roller. If machines could be constructed in such a way tha , immediately they took up, the draw commenced in a perfectly even position, there would be no form of rolling, and thus numerous difficulties which rolling created would be eliminated. The ideal form of sizing artificial silk, in his opinion, was by eliminating the comb which expanded the yarn from the box and by taking it over cylinders in the same way as cotton. It was undesirable to have the threads glued together. There was yet considerable room for the exercise of inventive genius to develop forms of mechanical sizing for artificial silk. As the lecturer was one of the authorities on such matters perhaps he would inform members what mixing he would suggest for ordinary use in the sizing of yarns for weaving purposes. Could he supply a formula for a standard mixing ?

Another speaker also referred to the actual mixing of the sizes. Gelatine, either in its purest form or broken down, had been frequently mentioned in the literature. What was the effect of such gelatine mixed with either maize or dextrin, and what was the effect on soft materials of such sizes ?

Mr. J. Hollas (Preston) inquired what was meant by the statement that artificial silk was puckered when the cloth was finished ? He also wished for more information about its having been stretched and not having gone back.

Mr. F. P. Slater (Bollington) asked whether any serious attempt had been made to control the temperature of the machines.

Mr. J. K. Kerfoot (Sidcup) wished to know how an even temperature was maintained on the plates. Looking at the matter from an economic point of view, it seemed to him to be next to impossible to maintain an even temperature.

Mr. Bean, in reply to the discussion, said he had endeavoured to make it quite clear that the starch used should be a treated starch, i.e., starch which had been rendered partially soluble. The general experience was that the use of either gelatine, dextrin, or gums such as tragacanth, was undesirable because of the tendency of the yarn to stick. With a partially soluble or thin boiling starch sticking was avoided. This was found out some years ago with bobbin-to-bobbin sizing. If thin boiling starch was used there was no sticking of the size, although used on a bobbin. When a dextrin was used there was a good deal of sticking. In regard to the stretching and the puckering, it was necessary to remember that two yarns, differing very considerably in properties, were being employed in one fabric. In the case of the cotton yarn very little stretching took place during sizing. In fact, in good sizing practice as little tension as possible was put on the yarn so as to retain its strength for weaving. In the case of artificial silk yarn, a considerable amount of stretching took place in spite of every precaution. The result of this was that when the cloth was wetted out in the bleaching and finishing processes, and dried under little tension, the artificial silk yarn shrank more than the cotton in returning to its original length as before sizing, and so caused puckering of the fabric. A point had been raised in regard to the temperature at which the size should be used for artificial silk yarns. As already mentioned, it was necessary to use the size at a fairly low temperature on account of handling, and this was the case when sizing cotton yarn in the hank. Even when the sizing of artificial silk was conducted in the machine it was better to use the size at a fairly low temperature, say 60° to 80° F. It was different in the case of cotton yarns, because such yarns are made up of a number of very small fibres twisted more or less tightly. In this case boiling the size was important, as the ebullition and movement of the size assisted materially in penetration between the fibres of the yarn. It is a well-known fact that cotton had a tendency to resist penetration on account of the natural wax and fatty matters present acting as water-resisting media. At the present time temperature control in sizing cotton yarns was advocated, but he was firmly convinced that "hard boiling" was the best temperature for cotton yarns. In answer to a question in regard to the temperature of the drying cells on the machine shown on the diagram, Mr. Bean said that evenness was maintained by the use of a series of baffle plates, but he would prefer that some engineer who knew the actual construction of the drying cells would offer an opinion about this point. There were no means of heating the size in the size box, as it had been found that hot size was not suitable for artificial silk. The size was heated to the temperature previously mentioned in the beck used for its preparation and then allowed to cool before being used on the machine. "Cold" was a matter of comparison; a few degrees of temperature were unimportant.

Mr. W. Frost (Macclesfield) said that, as an old silk throwster, he was sure that the practical hints given by Mr. Bean demonstrated the importance of

paying attention to details which, though apparently small, if neglected led to serious consequences. He moved a hearty vote of thanks to the lecturer. The vote was carried by acclamation and the proceedings terminated.

A group photograph was taken of the company in attendance at the proceedings.

CONJOINT MEETING AT LEICESTER

Meeting at Junior Training Hall, Leicester, 15th October 1926;
Mr. T. Fielding Johnson in the chair.

Promoted by the Committee of the Lancashire Section of the Institute, the above meeting was held conjointly with the Leicester Textile Society. A special visit to the Textile Machinery, Yarns, and Fabrics Exhibition, by kind invitation of the Exhibition Directors, was associated with the event, and there was an excellent attendance. Prior to the meeting tea was served by invitation of the Directors.

Mr. Frank Nasmith, Manager of the Exhibition, introduced Mr. T. Fielding Johnson as Chairman of the meeting, and said that he was extremely pleased that the Textile Society movement at Leicester, which probably dated from a meeting held at a previous exhibition of a similar character, had developed in a highly satisfactory manner. The Chairman that afternoon had long been particularly interested in technical education and they welcomed his presence. Proceeding, Mr. Nasmith made reference to the work of the Textile Institute and particularly to the scheme by which membership could be associated with post-graduate qualification.

The Chairman said that not only was technical education of vital interest to the young men concerned with the industry, but he recognised that it was of great help to Leicester as the centre of the hosiery trade. The hosiery industry was Leicester's original industry. He had pleasure in calling upon Mr. Herman S. Bell, of Nottingham, to give a paper on "Thread Take-up in the Seaming of Knitted Fabrics," which appears in the Transactions Section of this issue (T583–T587).

A brief discussion followed the reading of the paper, and Mr. J. Chamberlain said that Mr. Bell had made a good start and should go forward with the subject. The advantage of special calculations depended greatly upon the conditions under which work was being carried out. The lecturer said that although factory conditions differed, yet he had secured his results from conditions of normal standard—normal fabrics and normal conditions—and he had set out to secure accurate results. The meeting ended with a vote of thanks to the contributor of the paper, to the chairman, and to Mr. Nasmith, Mr. Wm. Bastard proposing the vote as representing the Leicester Textile Society.

TEXTILE TEACHERS' ASSOCIATION

The annual meeting of this Association took place at the Textile Institute, Manchester, on the afternoon of Saturday, 6th November, when Mr. E. Cousins (Leigh) presided. There were members present from various parts of Lancashire and adjoining counties. The annual report and financial statement were adopted, after which Mr. Cousins proposed the election of Mr. J. W. Adamson (Accrington) as President for the ensuing year, the motion being heartily carried. Mr. Walter Bailey (Ashton) was elected Vice-President. A sub-committee was appointed to meet a committee of the A.T.T.I. in order to discuss the question of the establishment of National Certificates in connection with textile training in reference to the cotton industry. Messrs. Thornley, Oldham, Atkinson, and Wilkinson were re-elected to the Committee of the Association, and Mr. C. Barnshaw

(Blackburn) was re-elected Hon. Secretary, whilst Messrs. Pennington and Atkinson were appointed to attend a meeting of the Textile Institute Crompton Committee to consider revision of the scheme of competition.

The President (Mr. Adamson), in the course of an address, reviewed the work of the Association, which, he claimed, had performed considerable work of useful character, whilst the interchange of experience owing to the existence of the Association had been most beneficial. He urged that no opportunity should be missed of strengthening the Association's connection with the Textile Institute. He thought all members should be in membership of the Institute and, after that, should seek to qualify for the Diplomas of the Institute. It was not sufficient that textile teachers should be satisfied with ordinary membership, and he was certain that in the near future the Diplomas in question would be of great value. It was quite evident that the Institute was determined to maintain a really high standard of qualification. It was conceivable, in fact, that the securing of a Diploma of the Institute would become quite a necessity to the teacher of the future. If teachers as a body took up membership of the Institute, they could then see to it that they were adequately represented in the matter of direction of the affairs of the Institute, the constitution of which was on quite a democratic basis. If the majority of teachers could succeed in obtaining the Diplomas, then the standard and the prestige of the textile teacher would be enhanced thereby.

Mr. W. Wilkinson (Blackburn) suggested that in the matter of interpretation of the results of scientific investigations, it might be possible to arrange for a short series of lectures for teachers, possibly by some member of the staff of the British Cotton Industry Research Association. He hoped the Committee of the Association would bear this matter in mind.

NOTES AND NOTICES

Council of the Institute

At the monthly meeting of the Council, held on Wednesday, 17th November, at Manchester, several matters of interest were dealt with. Reference was made to next year's Annual Conference of the Institute, to be held at Bolton during Whit-week, the conference to form a part of the proceedings in connection with the local celebrations which are to take place in reference to the Centenary of the death of Crompton, the inventor of the mule. Already the Lancashire Section of the Institute had prepared a suggested list of papers for the Institute Conference, such papers referring to the historical aspects of subjects suitable for association with the celebration proceedings. The question of the introduction of general subjects was raised, and it was decided that the Committee named be requested to offer suggestions for additional papers of a general description. The Council also discussed the question of the use of the letters F.T.I. and A.T.I. by members entitled to do so, and it was agreed that public use of the abbreviations should be encouraged, but that in the Journal of the Institute the use generally should only apply to contributors of papers and to authors, according to the individual desire of such contributors. The General Secretary reported further communications from the U.S.A. with reference to the recent proposal for the organisation of the American members of this Institute. Mr. Charles H. Clark, of Boston, as Hon. Secretary, had written stating that at a meeting of the members it had been decided, for the present, to form a club. A report in reference to this organisation will appear in our next issue. The decision to style the organisation a club, however, does not preclude the future consideration of the formation of a definite Section of the Institute. Mr. Clark has asked for information on this matter, and it was agreed that a reply be sent by the General Secretary, after consultation with Mr. Frank Nasmith. The

Association of Special Libraries and Information Bureaux is inviting membership and annual subscriptions. The chief object of this organisation is to facilitate the co-ordination and systematic use of sources of information in science, industry, commerce &c., and the Association occupies for its offices part of the premises of the Institute at 38 Bloomsbury Square, London. It was decided by the Council to take up membership at £2 2s. per annum.

The Institute and Invested Funds

The policy of investment in connection with the Foundation Fund of the Institute and the application of the annual revenue by way of interest to special requirements, has succeeded admirably. The Foundation Fund is continuously open for expansion, and the total has been considerably advanced even in the course of the last few years—a by no means favourable period for augmentation. Adverse conditions notwithstanding, the experience of recent years suggests justification in expectation of further gradual expansion of the fund. Last year, addition to the extent of £525 was effected, whilst in the current year a sum of over £80 has been credited to the fund. The process of strengthening the financial position of the Institute by means of invested funds is to be further pursued as a result of a recent decision of the Finance Committee approved by Council. In the past, revenue from Life Membership subscriptions has been credited to income at the rate of 10 per cent. of the amount each year. As from the commencement of 1927, all Life Membership subscriptions received are to be invested and the capital retained. Moreover, due to the advent of the scheme under which diplomas are granted to members, and to the large number of admissions to Associateships and Fellowships in the early period of operation of the scheme, exceptional income by way of fees involved has arisen. As the scheme proceeds the annual revenue from fees may be expected to diminish gradually. Therefore, after apportionment of expense in connection with the scheme for the current year, the credit balance is to be invested. As the Institute continues to develop, the demands upon its resources irresistibly advance, and though the policy of investment may present temporary difficulty, yet there can be little doubt as to the satisfactory character of the ultimate result.

Design and Structure of Woven Fabrics

The Institute's annual competitions, which commenced in 1919 following upon the Crompton memorial gift, the annual revenue from which is applied to the provision of prizes with a view to the advancement of design and structure of textile fabrics, now form a prominent and well-established feature of the activities of the Institute. Since the leading competition was embarked upon, many modifications of the conditions of the competition have been effected. Experience has suggested changes which the Committee in charge of the scheme has readily considered. Moreover, the Committee has repeatedly invited suggestions for improvement of the scheme. Recently a special conference was held, at which the conditions of the scheme were completely canvassed. The result is that important amendments will, in all probability, figure in the conditions, when issued, in respect of next year's competitions. Although the Committee have not recommended alterations of quite so drastic an order as some of the delegates to the conference apparently desired, yet they had to consider the expression of highly divergent views. The decisions of the Committee may certainly be described as representing a genuine effort to achieve a fully satisfactory compromise. A considerable reduction in the total number of patterns required from participants in the principal competition is intended to improve the position of evening or part-time students as against the position of day students. When the amended scheme is launched, it is confidently anticipated that all interests affected will give whole-hearted support to it.

Advanced Standard of Achievement

One thing is quite certain—the scheme has achieved definite progress in reference to its chief aim—advancement in design and structure. The contributions of competitors for the prizes for the current year are considered a decided advance on any previously submitted. When the specimens become available for inspection, a very greatly extended measure of interest in the exhibits should accrue. The Council of the Institute may be expected to extend the facilities for inspection.* Although the adjudication is practically completed, the results will not be officially announced—according to Committee decision at the time of writing this note—until the distribution of prizes, which will take place at the Institute headquarters on the 11th December, when the specimens will be specially displayed. If possible the exhibition of the specimens will be continued on the 13th and 14th December. In addition to the display of specimens in connection with the principal competition, there will be interesting exhibits in connection with the special competitions, including the first entries in respect of the special prizes for yarns due to the generous offer of Messrs. R. Greg & Co., of South Reddish, Stockport, who have provided a sum of £25 for three years for this purpose. Though the specimens received have been few in number, yet the result is regarded as providing a really satisfactory commencement of the new competition. It is hoped, too, that other firms or organisations may be induced to help forward the expansion of the Institute's programme of competitions in regard to textile productions.

Institute Library—Accommodation and Additions

The acquisition of the library of the late Professor William Myers, apart from the satisfaction of securing a permanent home for the collection, has proved an addition of definite value, but has so increased the accommodation required that the matter has had careful consideration by the Committees concerned, and ultimately by the Council. The questions of shelf-room and of cataloguing have been debated, and are to be dealt with in that order. Meanwhile, it may be useful to reiterate the conditions upon which members may obtain books and periodicals on loan from the library of the Institute. A period of seven days is allowed and the only charge made is that of refund of outward postage; the borrower, of course, returning the book at his own expense. Many of the Journals from which the abstracts that appear in the Abstracts Section of this Journal are made, are received at the Institute, and members desiring to see the originals may borrow them upon the terms quoted. From time to time, individuals and organisations make gifts of books and periodicals to the Institute, and it is with gratitude that the following are acknowledged—

"Transactions of the Manchester Association of Engineers," 10 vols., 1906-1914. Given by the Treasurer, Mr. T. Fletcher Robinson.

"Transactions of the National Association of Cotton Manufacturers, Boston, Mass., U.S.A.," Vol. 103-104. Presented by a Member of the Association through the Secretary.

"Journal of the Huddersfield Textile Society," Vols. 1, 2, 4, and 7-22. Given by the Society.

Some of the periodicals received at the Institute are bound for better preservation, and in certain instances almost complete sets of volumes are now on the library shelves, and it is thought that some member or members may be in a position and willing to complete the sets. The following first list of volumes required is published—

"Textile Mercury," Vol. I. (1889); Vol. 14 (1896); Vols. 30 and 31 (1904); Vol. 61 (1919); Vols. 62-66 (1920-1922); "Textile Recorder," Vols. for 1883-1887, 1901-1903, and 1913-1918. "Journal of the Huddersfield Textile Society," Vols, 3, 5, and 6.

Textile Institute Diplomas—Fellowships and Associateships

The following elections to Fellowships and Associateships of the Institute have been completed since the publication in our August issue of the previous list—

FELLOWS

BARNSHAW, Charles (Bolton).
CLAPPERTON, George (Tyldesley).
COWDEN, William James Wallace (Belfast).
CURTIS, Harry Percy (Manchester).
FEARNSIDES, Frederick William (Bradford).
FOULDS, Charles Frederick (Colne).
HALL, Archibald John (Congleton).
HOWARTH, William (Bolton).
KENYON, John William (Preston).
WEBB, William Hubert (Randalstown).
WILLIAMS, Denys Roger Hesketh (Huddersfield).

ASSOCIATES

BUCKLEY, George Hervey (Nottingham).
HAINSWORTH, Sydney Beetham (Hull).
HILL, Frank (Blackburn).
METTRICK, Beaumont (Huddersfield).
MOISTER, Arthur Eric (Bradford).
MUKERJI, Bejoy Krishna (Calcutta).
NEWSHAM, William (Westhoughton).
RIDDIOUGH, Harry (Manchester).
SPRECKLEY, Reginald Stafford (Shipley).
SUTCLIFFE, Harry (Hebden Bridge).
TWOHIG, John Patrick (Bradford).
WOOD, Frederick Charles (Manchester).
WOODMAN, Herbert (London).
YOUNG, William (Carlisle).

Elected to Institute Membership

At the October meeting of the Council, the following were elected to member ship of the Institute—John E. Barbour (Linen Thread Manufacturer), c/o J. E Barbour Company, Paterson, N.J., U.S.A.; Norman Collinson (Assistant Wool Buyer), 8 Gladwin Street, Batley; J. L. Feather (Company Secretary and Director), 51 Bolling Hall Road, Bradford; J. M. Gericke (Textile Student), Technical College, Bradford; J. B. Gillett (Textile Student), South Villa, Bolton Road, Chorley; David D. Gray, junr. (Manufacturer and Director), Glenpark, Port Glasgow; Harry Hardy (Head of Textile Department, Dewsbury Technical College), Rods Mills, Morley; George Lawrie (Textile Engineer), 103 Cliftonpark Avenue, Belfast; W. Leeming (Textile Machinery Draughtsman), 62 Haywood Street, Accrington; James McClenaghan (Factory Manager), 316 Springfield Road, Belfast; Francis McEvoy (Manufacturer of Linen Damasks and Woollen, and Worsteds), Albert Street, Lurgan, Co. Armagh; Fred Morris (Textile Draughtsman and Teacher of Textile Engineering), 1 Ashbee Street, Astley Bridge, Bolton; James B. B. Morton (General Manager of Catrine Cotton Works and Bleaching Works), Ayrbank House, Catrine, Ayrshire; Joseph Parkinson (Mill Manager), 72 Chorley Old Road, Bolton; Leslie F. Pickup (Assistant Manager, Cotton Doubling and Weaving), Ibbotroyd, Wadsworth, Hebden Bridge; Fred Westhead (Cloth Salesman), c/o Wm. Westhead & Sons, Ltd., Salford Bridge Mills, Clitheroe; and James H. Yates (Textile Designer), 65 Milton Street, Nelson.

REVIEWS

Some Information about the Egyptian Cotton Market, Futures and Spot. By G. D. Economou & Co., Alexandria.

This is a very useful little handbook, containing a great deal of information about Egyptian cotton in general, and the Alexandria market in particular. It deals clearly with many of the technical matters in the cotton market of which the ordinary layman is ignorant and about which it is often very difficult to get accurate information. The book will be useful to many in the Liverpool and Manchester markets who are interested to know the differences in practice between these markets and Alexandria. A similar book dealing with each of the other principal cotton markets in this country, as well as in America and India, and on the Continent, would be very welcome. The book also contains a number of useful statistical tables with regard to the Egyptian crop since 1910, which will make it of permanent value for reference. In going through these we have noted only one slip—the acreage figures given for 1922 and 1923 are those of earlier estimates which were subsequently revised. There are also two useful maps of the Delta and Upper Egypt respectively, and interesting charts of cotton prices in Alexandria, as well as forms of the contracts commonly used in the Alexandria cotton market and an index. —J.T.

Modern Industrial Tendencies. By Sir Charles Macara. Published by Sherratt & Hughes, Manchester (253 pp. and Index; price, 5s. net).

This book of collected writings, the second that has appeared within the last twelve months, is a testimony to the vigour of Sir Charles Macara. Like its predecessor, it is mainly concerned with the question of control of the cotton trade, as a way out of its difficulties. The case is restated and the appeal for more publicity as to stocks and production of cotton yarns is made again with equal force. To the reviewer this appeal appears to be a matter to which the trade should give its closest attention. If any industry has suffered from working in the dark—and all have, and most still do—that trade is our own. The delicate adjustment of demand to supply is a matter of primary importance to Lancashire, and until there is knowledge of the facts, and not mere guessing, there cannot but be recurring dislocation. One cannot feel the same sympathy with Sir Charles Macara's advocacy of control. Let us have what the Americans call "orderly marketing" by all means; but any expedient that serves to bolster up the inflated capital of most cotton spinning firms is bad. Lancashire will never recover her markets until she can produce more cheaply; and the heavy fixed charges created during the share boom are one of the factors standing in the way of this. Sir Charles, in his spirited reply to persons who criticise the reflotation of mills, appears to miss the point. Quite obviously, it is not ordinary share capital that keeps up prices, since its return depends entirely upon the relation of turnover to costs of production, and is not itself a first charge upon the industry. What matters is the dead weight of loans and bank charges which came into being with, or as a result of, the reflotation of spinning mills. The greater part of this loan money is performing no useful function; it is dead capital, bearing no relation to the earning capacity of the industry. Control might provide a means of meeting these charges through monopolistic extortion, but any such plan would inevitably strengthen the already formidable competition from producers in India and Japan, and hasten the development of domestic production in other markets. Henry Ford, in his book "To-day and To-morrow," has some interesting things to say about dead capital. The first thing Lancashire has to do, if it is not too late, is to get rid of it. There is more point in what Sir Charles says about the effects of weak-selling upon trade. While this exists, hand-to-mouth buying is unescapable. Basis yarn prices may assist in mitigating this trouble, but there is no means of removing it except a wholesale reconstruction of the capitalisation of the industry. If basis prices are effective in providing profits, these profits must first of all be devoted to repaying loans and bank advances. If they are distributed in dividends there will be a temporary appearance of success, but the consequence will be a decline in the demand for cotton

goods. Very cheap raw cotton may help things out for a time, but it cannot be relied upon to do so for ever. The future of the trade depends upon lower prices and any control scheme that stands in the way will be disastrous. Sir Charles' book is well worth reading, but one would recommend that of Henry Ford as an antidote. —C.H.M.

Allen's Commercial Organic Analysis. Fifth Edition. Vol. III. Published by J. & A. Churchill, London.

The publishers are performing a valuable service in keeping this well-known work up to date. The volume under review deals with Hydrocarbons, Bitumens, Naphthalene and its derivatives, Anthracene and its allies, Phenols, Aromatic Acids, Gallic Acids and derivatives, Phthalic Acids and Phthaleins, and Modern Explosives. Under "Phenols" is included a valuable section on disinfectants, while under "Phthaleins" is a modern account of indicators. In order to keep the size of the volume within bounds, the section on Benzol and its homologues has been transferred to another volume, along with dyestuffs. It is unfortunate that this has been deemed necessary, as one would naturally look for Benzol amongst the other aromatic hydrocarbons. As it stands, however, the volume is a mine of information on the properties and methods of analysis of the substances concerned, and should be in every commercial organic laboratory. —R.G.

Hosiery Yarns and Fabrics. By John Chamberlain, Leicester. Published by J. W. Hemmings and Capey.

Students of the knitting industry will welcome Volume II. of a series of text books being prepared for the Textile Trades Advisory Committee of the City of Leicester Colleges of Technology and Art. The fact that the author of this work was joint author of several books on the subject of knitting, now unobtainable, will commend it to those interested in the industry. The book opens with a chapter on raw materials consisting of natural and artificial products, and the essential qualifications of those products for the manufacture of knitting yarns. Twelve pages are allotted to sources of supply, classification, microscopical examination, characteristics, and composition of animal fibres. Seven pages are devoted to vegetable fibres, and three pages to artificial fibres. The hollow artificial fibre referred to is known as "Celta," and produces a fabric easily distinguished by its softness of handle. Chapter II. classifies the yarns manufactured from the various fibres according to "count," "fibrous composition," "spinning and doubling operations," "finishing, bleaching, and dyeing"; furnishing tables of the numerous single fibred yarns under the various headings of wool, cotton, silk, &c. Whilst the author acknowledges that spinning is a subject to itself, the many processes through which the fibres must pass in their conversion into yarns are treated in a manner likely to tempt the student into securing a deeper knowledge of the subject. The blending of fibres and yarns to produce mixtures and fancies is also included. Yarn testing is then dealt with and covers "recognition of fibres," "testing for counts," "twist," "condition," "strength and extensibility," and giving interesting examples of actual tests and results. Chapter IV. on yarn winding rightly emphasises the importance of this operation, dealing with lubricants, knot-tying, &c., and providing twelve sectional diagrams of machines used in the winding of every conceivable type of yarn for knitting. A diagram is also given of a back-winding machine for the recovery of yarn from imperfect fabric, and a warping mill. Chapter V. opens with a brief description of the production of a woven fabric by means of the "intersection system" and of the "twisting system," as adopted in the manufacture of lace. The diagram of the twisted lace fabric is better known as bobbin net and is made on a two-tier carriage machine of the rolling locker or double locker type. In describing the "looping system" on which knitted fabrics are constructed, the writer gives a clear definition of the weft and warp fabrics, then sub-divides the three primary stitches used in weft-knitting. The arrangements of these stitches in the first diagram is very effective and is followed in this chapter by nine really lucid diagrams, which include binding off, linking, wale-narrowing, roll-welt, racked-welt, plain-plated, and twisted loops. Chapter VI. gives a list of twelve fancy stitches, most of which are admirably illustrated,

and followed by over 50 designs on flat and purl machines. Chapter VII., on warp-knitted stitches, is of special interest. The distinction in the structure as compared with weft stitches is clearly demonstrated, and includes a list classifying close warp fabrics in comparison with weft knitted fabrics. Commencing with the simplest lap producible, the writer deals with the drafting of designs, showing diagrams and interpretations of the various laps used in the making of several well known warp fabrics. The making up of knitted fabrics into the finished article requires machines specially adapted to this branch of the industry. The closing chapter mainly deals with the numerous stitches employed in joining up various types of knitted fabric. Questions set at the close of each chapter will enable the student to test his knowledge of each subject. The book will be found very helpful. —G.H.B.

GENERAL ITEMS AND REPORTS

Standardisation in the Textile Trade

Mr. A. M. Samuel, M.P., Parliamentary Secretary to the Department of Overseas Trade, gave an address on "Some Aspects of Overseas Trade" before the Bradford Textile Society on Monday, 1st November; Mr. Arthur Hitt, President of the Society, occupying the chair. Mr. Samuel referred to the danger of a shortage of raw natural silk, and appealed to his hearers to do what they could to foster production within the Empire. As result of the efforts of the Silk Committee at the Imperial Institute (which was now linked up with the Department of Overseas Trade), Cyprus, which was under British rule, was producing excellent raw silk, the cocoons being reeled there instead of dealt with by filature at Marseilles, as had hitherto been the case. Experiments had proved that raw silk could be grown in several parts of India and in Irak, Jamaica, Kenya, Rhodesia, and Hong-Kong. Just as the production of rubber had brought great wealth to the British Empire, so could the production of raw silk be fostered within our Dominions to the profit of all. There was every prospect of a world shortage of supplies of raw and waste silk, and unless that state of affairs was remedied it would have a serious result on the British silk industry, especially as America would continue to bid for the bulk of the available supplies, particularly those of higher quality. He did not think that artificial silk was likely to affect the demand for real silk goods, except possibly the lower grades. Another question he wished to bring before their notice was that of standardisation. Standardisation might not seem to be applicable to Bradford, because changes of fashion in dress were desirable as a source of profit. Nevertheless, the National Association of Outfitters was already pursuing a policy of standardisation of sizes in men's underwear, and in the ladies' shoe trade the policy was being discussed. It had often been stated that we tried to force on our foreign customers the sizes and varieties we wished to sell, rather than those they wished to buy. He thought the accusation was, in many cases, unfounded, and the fact was that the choice we gave to them was unnecessarily diverse. The tendency to standardise articles was growing in other countries, and we must keep abreast of such developments.

Mr. F. Hopkinson, in the course of the discussion, said he did not see how the standardisation of Bradford or Manchester products would help in obtaining trade in overseas markets, because the demand of the world would always be for novelties, and other countries were producing them.

Mr. Samuel said he did not think the textile trade provided a good example of an industry that would benefit from standardisation. Standardisation for the home trade, however, would reduce overhead charges and enable products to be sold more cheaply, thus facilitating the production of greater variety for export. Other countries were showing novelties abroad and reducing the variety of patterns at home.

Mr. John Emsley said in the past Bradford had made a great mistake in telling foreigners either to take the goods or leave them. When they refused to make a fresh pattern for a customer, someone else stepped in and took the order. Standardisation was all right so long as there was a certain number of people prepared to dress all alike, but in England variety was wanted. They were catering not only for the Bradford market, but for every market in the world,

English and Continental Systems of Worsted Drawing and Spinning

Mr. S. Kershaw, of the Bradford Technical College, addressed a meeting of the Huddersfield Textile Society at the Technical College, Huddersfield, on Monday, 8th November, on the subject of "Recent Investigations in Worsted Drawing and Spinning." An investigation carried out recently, said Mr. Kershaw, had shown that drawing might be considered the most important of the sequence of operations from the top to the finished fabric. Yarns and cloths drawn by the Continental method had valuable properties not possessed by materials drawn by the open or cone methods; the Continental method in all instances produced stronger and fuller yarns and cloths. Probably the greatest step forward that the worsted industry of Yorkshire could make would be to put down more machinery for working short fine wools into yarns suitable for soft-handling dress goods and hosiery fabrics. The benefits to be derived by worsted spinners if yarns were manufactured in this country on the Continental system would be that cheaper raw materials could be used to produce equally good if not superior yarns to those obtained by existing methods. By the use of the Heilmann comb, porcupine drawing, and mule spinning, very short wools could be made into worsted yarns. Yarns produced on these machines possessed excellent handling properties suitable for hosieries. For certain types of wool the Continental system was the only system for conversion into worsted yarns. From the fabric point of view the Continental system was superior to the English system. Openness of fibre arrangement permitted better manipulation in dyeing and finishing. The Continental system was recommended as a supporter and not as a supplanter to the English method. If there were more porcupine drawing sets followed by either the mule or the Continental ring frame, many wools difficult to process on open and cone machines would be re-directed, and better and more easily manipulated. While not claiming that the Continental ring frame was as good as the mule for spinning fine counts, yet splendid results were obtained in thicker yarns for hosiery purposes. The simplicity of the machine assured it a place in the industry, and when it was considered that wool two inches in length could be controlled and made into level yarns, its usefulness needed no emphasis. The spirit of investigation was still needed to settle many problems in worsted yarn manufacture. While making the most of existing processes, we should not be afraid of experimenting, as many secrets might be revealed which were at present unknown.

Replying to a vote of thanks, Mr. Kershaw said they were reaching a point where many things might happen to the Huddersfield trade. Artificial silk was coming into Bradford and being combed into tops, sometimes alone, and sometimes combined with wool. Yarns were being produced containing 50% of silk and 50% of wool. The pieces produced were sent to the dyer, who returned from one good piece about twenty shades of coloured mixture cloths, the silk taking one colour and the wool another. Huddersfield was noted for its coloured trade, but it might so happen that it might be supplanted by this silk and wool mixture.

THE JOURNAL OF THE TEXTILE INSTITUTE

Vol. XVII DECEMBER No. 12

PROCEEDINGS

Luncheon Meeting of the United States Members of the Textile Institute, Copley Plaza Hotel, Boston, Mass., 13th October, 1926.

A luncheon meeting of members in the United States of the Textile Institute, and the first general meeting of these members, was held on 13th October at the Copley Plaza Hotel, Boston, pursuant to the call of a "Committee of Arrangements" made up of members in and near Boston, of which Franklin W. Hobbs was Chairman, this meeting having been held in Boston, 17th September. Those in attendance were as follows—Franklin W. Hobbs, Boston; Charles H. Clark, Boston; Edmund E. Blake, Biddeford; James T. Broadbent, New York; R. H. Brown, Boston; A. G. Denis, Webster; Daniel E. Douty, New York; George L. Gilmore, Somerville; G. Van Tromp Govier, Decatur; F. J. Hoxie, Boston; Edwin H. Marble, Worcester; C. E. Mead, Boston; Brackett Parsons, Boston; Frank W. Reynolds, Boston; Charles W. Schoffstall, Washington; J. Tattersall, Boston; A. M. Tenney, New York; E. D. Walen, Lawrence; Harold D. W. Smith, New York; and Mr. Weston Howland, Assistant Treasurer of the Warwick Mills, Centerville, R.I. To make the most of the brief time until the convening of the first session of the convention of the National Association of Cotton Manufacturers, to which Institute members had been invited, the acting Chairman asked the acting Secretary—Mr. C. H. Clark—to make a report of events that had led up to this meeting. In the course of this report Mr. Clark referred to the letter-vote of members reported at the meeting, 5th August, giving the views of 22 members on the subject, three of whom opposed any new organisation, five favoured a branch of the Textile Institute in this country, five favoured some separate organisation for the promotion of research work, and nine stated that they would abide by a majority decision. Mr. Clark stated that correspondence and personal interviews with members since then had altered the vote of these 22 members as follows—two opposed to any new organisation, sixteen favoured a branch of the Textile Institute, one favoured a separate organisation, and three were willing to abide by a majority decision. Of 29 members who had expressed an opinion either by mail or in person, 26 were either in favour of a branch of the Institute in this country, or would abide by majority decision on the subject. Expressing his personal views on the subject of organisation, Mr. Clark stated that his correspondence and talks with members had impressed him with the fact that they represented a little group which had been brought together automatically by their interest in research as expressed by their membership of the Textile Institute, largely for the purpose of obtaining copies of the *Journal of the Textile Institute*, with its reports of British textile work. The leading textile associations in the United States from time to time had had Research Committees, but at present these were either non-existent or inactive. None

would dispute the advantage to the industry of the future of research work, and he felt that some one body having the development of research work as its chief objective would prove of great value to the industry, and that the members of the Textile Institute in this country were the logical *nucleus* of such a body. Its present membership would give such an organisation contact with every important textile association and present source of textile research work in this country, and also connection with the parent body in England, which might prove of mutual advantage. He did not think it mattered much at the start whether the members came together as a section of the Textile Institute or as a separate organisation, but hoped that some form of organisation could be given a trial, feeling certain the membership could be largely increased and that the organisation could be made a powerful factor in stimulating interest in textile research work.

The Chairman agreed in large part with what Mr. Clark had said, and felt that there were important opportunities for an organisation composed of the Textile Institute membership in this country, but he was not certain as to the best form of organisation. He read a letter addressed to him by President Calvin Rice, of the American Society of Mechanical Engineers, of which he is a member. President Rice's letter said that he had heard of the movement for organisation of a branch of the Textile Institute in this country, and expressed the hope that its membership would find what it needed in the textile section of the A.S.M.E. Chairman Hobbs then asked for a general expression of opinion from those present as to the form of organisation and the function of the body.

James T. Broadbent (New York) felt that it would be unfortunate if those who represented such an important organisation could not get together and find a real service to perform for the industry. He felt that the form of the organisation was of the least importance. He thought that Mr. Athey's letter of 23rd September to Mr. Clark ought to be accepted at its face value, and that organisation of a branch or section might be delayed until there was a larger membership. In the meantime it would be well to learn what obligations to the parent organisation were involved by the organisation of a section. He thought it would be sufficient at present to get together once or twice a year; that if a title was needed the group might be called the Textile Institute Club.

E. H. Marble (Worcester) could see no possible conflict between the membership of the Textile Institute in this country organised as a section or a club and the textile section of the A.S.M.E., or with any other existing textile organisation. He believed that there was a big field for such an organisation, stating that among its functions could be the development of an international nomenclature for textiles.

F. W. Reynolds (Boston) stated that he liked the club idea, and suggested that it might be called a Textile Research Club.

E. E. Blake (Biddeford) also approved a club idea, and suggested the title "American Members of the Textile Institute."

D. E. Douty (New York) stated that he knew of no Textile Association that is now giving serious and constant attention to the development of research work, and that in this group of men who had been brought together by this subject it ought to be possible to perform a real service for the industry. There should be no duplication of the work of other associations, and he believed that this could be easily avoided. He also believed that the form of the organisation was of less importance than the act of organising.

J. T. Broadbent then moved, and Edwin H. Marble seconded, the organisation of the Textile Institute Club, the Secretary being instructed to learn whether as a section of the Textile Institute there would be any obligations to be assumed. Upon being put by Chairman Hobbs, the motion was carried unanimously.

Chairman Hobbs then presented on behalf of the "Committee of Arrangements" for this meeting the following suggested committee and officers of the

new organisation, stating that the names were selected with the idea of giving contacts with all of the leading textile associations as far as the present membership made possible—George L. Gilmore, Chairman; James T. Broadbent, Vice-chairman; Charles H. Clark, Secretary-Treasurer; Franklin W. Hobbs, Edwin H. Marble, E. D. Walen, A. M. Tenney, Brackett Parsons, D. E. Douty.

E. E. Blake moved that the Secretary be instructed to cast one ballot for the ticket, and that the committee members and officers hold office until succeeded. This being properly seconded, the motion was carried unanimously, and Secretary Clark cast the ballot as instructed.

Acting Chairman F. W. Hobbs then turned the meeting over to Chairman George L. Gilmore, and the latter, after thanking the members present for the honour conferred upon him and promising to perform the functions of his office to the best of his ability, expressed regret that Franklin W. Hobbs had felt it impossible to accept the chairmanship. He then suggested that, for the purpose of covering correspondence and other secretarial expenses, an assessment of 5 dollars be made on each member of the club, this to cover the luncheon also. Upon being moved and seconded, the motion was carried unanimously. The meeting was then formally adjourned subject to call of the committee.

In the informal discussion that followed the hope was expressed by many that the next meeting could be held at the time of the next spring convention of the National Association of Cotton Manufacturers, if not before, and that it might be possible to hold group meetings in Boston and New York, in the interim, of members in and near those centres.

Yorkshire Section

Joint Meeting with the Halifax Textile Society, 20th October, 1926;
G. W. Haigh, Esq., in the chair.

TOPMAKING—DO ENGLISH METHODS PAY?

By R. G. Bailey, F.T.I.

With regard to topmaking and the question, "Do English methods pay?" I have no doubt that some of you have already answered that question in your own minds. You have been thinking of a few of the large topmaking concerns of Bradford and district—firms which from small beginnings have grown into marvellous organisations with world-wide reputations. My remarks this evening, however, are not concerned with the profits of individual firms. It is from a national point of view—not that of the individual—that I wish to consider the matter. I want to consider whether our methods of topmaking are the best for the country. Are they sound methods, are they economical, or is the present procedure wasteful from a national point of view? Much of what I wish to say relates to the economical use of raw materials. When I speak of the waste of materials I do not mean actual waste of wool in topmaking, or waste as known by the trade in the spinning and weaving processes, but if for one reason or another in any finished fabric—be it woven fabrics or hosiery—a type of wool is used better than that necessary to produce the finished article, then national waste has taken place.

The subject of topmaking cannot adequately be dealt with in half an hour's talk, and it will be impossible to consider more than one or two special features. I want first very briefly to consider present methods; then a few of the disadvantages which are inherited from present procedures by all engaged in the later operations, that is, spinning, weaving, as well as dyeing and finishing; and finally to submit some suggestions which, if carried out, would obviate, in my opinion, many of the present difficulties. Specialisation has become increasingly prevalent in the wool textile trade of England, especially in the

worsted section. There are still many spinners who make the bulk of the tops they use, and a few firms which buy the raw wool and put it through all processes to the finished fabric, but the greater part of the tops made in this country to-day are produced under the control of topmakers, whose function ceases when they sell the tops to a spinner, to a dealer, or to an export merchant. Owing to the tremendous variety of wool types, topmakers are divided into different categories, the chief of which are merino, crossbred, and English. In some cases, particularly with the larger firms, a firm may make all three types, but this is the exception rather than the rule.

Briefly stated, it is the vocation of a topmaker to buy wools as cheaply as possible, either in the primary markets of the world—Australia, New Zealand, the Cape, South America—or in London or locally; to sort them as to suitability for the making of his standard range of tops, and to blend them so as to produce tops as nearly as possible of the same quality as previous lots. If a Bradford wool buyer were sent to London with a limit of, say, 4s., for 64's warp tops, then generally, if the wool suited his requirements regarding length and quality, it would not matter whether it came from Melbourne or Adelaide. Spinning properties are only a secondary consideration to fineness of fibre and length, and the limit at which he has to purchase. Some topmakers never use wools from South America or wools from the Cape, but confine their blends to, say, Australian or New Zealand wools. Others never purchase "scoureds," and quite a number refuse to use "skin wools," but even the topmakers making the very best tops invariably blend wool from different parts of Australia to make their standard. With very few exceptions tops made by topmakers in the West Riding are all of a blended nature.

There are two main objects in blending—first, to obtain certain effects in the yarn and the cloth; second, to cheapen the top. With regard to the first, success can only be assured when the blender knows the spinning and felting properties of his wools. With regard to the second, when blending is undertaken to cheapen the top, the faults of working to a price are manifest. A good top might be made one year from a good blend. The following season the price factor alone might rule out that particular blend. There is, of course, the striking example of Cape wool. Cape wool was primarily used as a cheapening element, whilst now it is relatively dearer than Australian. Even the largest firms in Bradford, if Melbourne and Adelaide wools come in at the same time, might make a fifty-fifty blend. They might make a 100% Victoria but seldom would make a 100% Adelaide; that is to say, on one occasion an article composed wholly of wools from Victoria is delivered, whilst on another occasion the top may be a blend of Adelaide and Melbourne wools. Both deliveries would be sent as equal and against a so-called standard.

Spinners naturally are aware that practically all the tops they purchase are made from blended wools, and immediately the spinning properties of any top they receive prove inferior to the spinning properties of a previous delivery of the same quality, a complaint is made. The spinner, probably having heard many years ago that Cape wools and wools from South America are inferior to those from Australia, immediately concludes that these wools have been mixed in by the topmaker. Many years ago it was an undoubted fact that Cape wools and wools from South America were inferior in almost all their properties to the Australian products, but during the last twenty years Cape wools, and certain types of South American wools, have improved almost beyond recognition, but, as in some instances, the spinner in the meantime has had no opportunity of getting to know the improved properties of these wools, he still retains his old prejudice against them. The wools of South Africa are being appreciated more to-day by Bradford topmakers and spinners than ever before, but even to-day I am satisfied that many firms have not given Cape Wools a fair chance. For hosiery fabrics, Capes are being used in increasing quantities, and

one cannot help but point to the big weight of short Cape wools which are being spun on the Continent and sold to Leicester hosiery manufacturers. This also applies to Chubut wools of South America, nearly all of which are shipped to the Continent for spinning into hosiery yarns. Apart from Punta wools, few, if any, topmakers in the West Riding admit that they use South American wools, but nevertheless many topmakers buy South American wools for topmaking purposes, and at a conservative estimate more than 50% of wool used to make 46's and lower prepared tops is of South American origin.

At the present time the topmaker selects from various countries wools with equal blending qualities, such as length, fineness, and character, and he must be able to repeat standard deliveries at all times, this being one of the most vital points of all. I have never forgotten having it drilled into me at school that the composition of a chemical compound was constant. Topmakers make standard tops, but however good their intentions may be, the deliveries obtained at different times vary. In a chemical compound the components are always the same, but the finest and most careful topmaker would never claim that his tops—one delivery compared with another—were absolutely identical. In sorting, for instance, personal judgment has to be used, and therefore differences are bound to result.

If all wool were alike, if there were no such things as difference in breed, in fineness of fibre, in length, strength, and handle, &c., then the economical manufacturing of wool textiles would be almost entirely a question of economically running the machinery. As, however, there are a thousand different kinds of wool, one factor which ranks at least with equal importance to that of the economical running of machinery is the correct choice of the raw material for the effect and article required. Knowledge of topmaking, spinning, and weaving is further advanced on the mechanical side than on the material side. Commission wool combers in the West Riding of Yorkshire have tried unceasingly to perfect the art of woolcombing, at least so far as the usual English systems are concerned, and large sums of money have been spent in research work, but commission combers are only concerned with the machinery side of topmaking. No matter how much research is undertaken by the comber, it can only be on the manipulative side—the machinery side of topmaking. At the other end of the trade one has the cloth finisher, and I think it can safely be said that probably in no other country in the world has so much experimental work been undertaken with regard to the finishing of textile products as in this country.

Although it is admitted that the weaving loom is one of the most unscientific machines used in the textile industry, people have tried for generations to im prove it in order to make a more perfect cloth. It must be realised that the perfect cloth can only be obtained when the manufacturer gets the perfect material for the ultimate fabric in view. Machinery improvements certainly are essential, and in the textile trade there appears to be much scope still for inventive genius, but the most perfect machines in the world, managed by the most experienced workpeople, will not prove successful unless the correct material is being used. I contend that to-day faults in the finished article are not infrequently due to the wrong selection of the raw materials rather than to bad workmanship in the processing of the material.

It must be admitted that certain wools are more useful than others for obtaining certain effects in cloths, but a topmaker could not be expected to know much, if anything, about that. He has no chance of getting to know, and this, I think you will agree, also applies to the spinner to much the same extent. Some spinners, of course, do occasionally see the cloths into which their yarns have gone, but, generally speaking, I think that when a spinner receives an invitation from his customer to inspect the fabrics being made from his yarns, the invitation creates a somewhat nervous feeling, because more often than not such invitation is only made in order to put before the spinner some complaint.

It has been said that manufacturers do not know a great deal about classes of wools other than those which they themselves use. In the case of worsted manufacturers the majority are not in a position to know even the origin of the wools they are using. It is of vital importance that manufacturers should get to know the actual properties of various wools and the uses to which they are most fitted, but this is impossible so long as spinners are compelled to use blended tops, and manufacturers, as a net result, receive yarns containing a conglomeration of greasy, scoured, and skin wools from Australia, the Cape, and South America. I think you will realise that as the properties of wools do vary, it is possible to mix together wools of different types which may be working against each other, if not in the combing or even the spinning, perhaps in the finishing operations. The foundation of the West Riding wool textile industry was laid by manufacturers using British wools grown upon the neighbouring hills, and they learned thoroughly the properties of the various British grown wools. The West Riding textile trade would never have assumed its present proportions but for the wools of our Colonies, but I am confident of this, that the present generation do not know as much regarding the properties of Colonial wools as their forefathers did regarding English wools. The trade has standardised, but there is one thing which standardisation has done in Bradford; the trade has knocked itself out of the running for producing yarns and fabrics such as those from France and Germany. If you make a point of using a uniform fibre and not mixing it for certain classes of fabrics, you will get a better result and a result which cannot be obtained by mixing. If we are to make such fabrics as the French make it will be necessary to go right back to the sheep, buy the wools, and, without blending, carry them through all the processes to the finished article. Our Continental rivals have done this, and have evolved a type of machinery suitable to the requirements of the wools which they use. Everyone admits that care must be taken in the choice of materials, but seldom, if ever, is it possible to get any further. Under present procedure it appears impossible to get to know with absolute certainty the type of material best suited for a particular fabric. I contend, however, that just as there is one exact place on the violin string on which the finger must be placed in order to produce a particular tone, so there is a particular raw material which must be used to attain any specific result. For instance, who in England to-day could, with conviction, tell us what wools to use for certain cloths, or which cloths to make from various wools? Certainly not the wool merchant or top maker.

The woollen designer—and in many cases the worsted designer—to be fully competent, must be a materials expert. In woollen cloth designing, even more so than in worsted manufacturing, the raw materials must be carefully selected, always bearing in mind the finished effect required. I remember, as a student at the Bradford Technical College, repeatedly being told that a woollen fabric was more or less made in the finishing. This is undoubtedly true. In woollen cloth designing the milling and felting properties of wools have to be specially considered, and it is essential that the finisher should know the wools being used. In England woollen manufacturers enjoy a special advantage over worsted manufacturers in that they select their raw material, make their own blend, keeping a record of quantities and qualities and values right through the processes.

So far I have tried to show some of the disadvantages under which spinners and manufacturers in this country are compelled to work. Disadvantages due to the fact that they are more or less compelled to use raw material the origin of which is unknown to them. Yet it is an admitted fact that wools of the same quality but grown in different districts vary considerably in their spinning and manufacturing properties. A change in fashion is probably more serious to the West Riding textile trade than to the industry in France and Germany, because in this country the designer is less familiar with the special properties of certain

wools, and he therefore takes more time in achieving the desired result. A manufacturer may get a yarn which produces the cloth required, but not at an economical price. If we are to regain our premier position in the world's markets, then much greater thought will have to be given to the utilisation of the correct material to make the best article at the lowest price consistent with quality and good workmanship.

There are many fallacies regarding blending, and these are bound to continue until research is undertaken to determine the properties of various wools. This can only be carried out by a very much closer co-operation between topmaker and spinner, weaver and finisher. Fallacies regarding blending will remain so long as topmakers continue to supply standard tops the wools of which are of unknown origin—at least to subsequent users. It is certain that our Continental competitors appreciate to a fine point the various properties of the many types of wools. The French and Germans, for example, appear to specialise individually in certain types of yarn, and take full advantage of the divergent properties offered to them in the raw material. In Germany, where tops are made by topmakers and combed by a commission woolcomber, blending does not take place. Montevideo wools, for example, are not mixed with Australian or with any other wool. Even different types of South American wools are kept quite separate in the combing. Sorting is carried out under the control of the commission comber, and he is in a position to give a certificate of origin with regard to the wools being used—a guarantee of the raw material employed. I maintain that this is the only scientific way of topmaking from a material point of view, because under a procedure of this kind the spinner is in a position to know exactly what he is using, and this information can be passed on to the manufacturer whether of pieces or hosiery.

Foreign competition is on the increase. New countries buy the latest machinery. They may be handicapped for a time by the necessity of employing unskilled and semi-skilled workpeople, but very soon their workers become efficient and competition between this country and others naturally will become still more keen. England possesses the lead by reason of our well-trained operatives and the inborn skill of our workers, and this advantage must not be frittered away by using less up-to-date machinery, or, what is equally important, a disinclination to adopt new methods.

In any industry there are three partners—capital, management, and labour—and I believe at the present time that management is the most important factor of the lot. It is management which is the bedrock of more efficient production. It is not sufficient for the management just to know their own individual line, but what goes before and what follows, and in the industry as conducted in England at the present time there is, in my humble opinion, much scope for improved methods. I have tried to show how closer co-operation might be brought about between various sections of the industry—something which is essential from a national point of view, and I am firmly convinced that with this co-operation and a better understanding of the requirements of users, this great industry, of which we are all so proud, could yet lead the world.

London Section

Discussion Meeting at the Institute's Rooms, 38 Bloomsbury Square, W.C.1, 10th November 1926. Chairman, Mr. E. Wigglesworth.

DECORATIVE SILKS—THE DEVELOPMENT OF DESIGN

The Chairman, introducing the Lecturer, explained that Mr. Woodman was a member of the firm of Warner & Sons, of Newgate Street, which firm had the reputation for manufacturing the finest decorative and furnishing fabrics in this country.

Mr. Woodman said—I shall attempt to give a brief sketch of the principal styles or periods in furnishing silks and similar fabrics. As so many of the famous designs of the 14th–19th centuries are being reproduced in modern fabrics it is only natural that a greater interest is being taken in their origin than at any previous time. The original artists of these period designs could never have imagined how, in the 20th century, their works would be reproduced in such vast quantities, chiefly in fabrics which are within the purchasing range of the average householder. To follow the development of these popular styles successfully, it is helpful to trace some of the great influences which have affected them, so perhaps a few words on the ancient silks will not be out of place. I might say that it is impossible to draw fine dividing lines between the various periods; there is nearly always what one might call a "merging" style where we find the old and new influence both present. According to Chinese tradition elaborate silks were being woven many centuries before the Christian era but no pre-Christian examples have been preserved. I believe the oldest in existence are some pieces found in a Chinese-Turkestan tomb of between the 1st and the 3rd Centuries A.D. They display the most remarkable animal designs drawn in a free style and not far removed from Chinese designs woven centuries later. The secret of sericulture was carefully guarded by the Chinese until the 3rd Century A.D., when Khotan, Japan, and India are supposed to have discovered it; not until the year 552 A.D. did the people of the Near East solve the mystery, when two monks smuggled silkworm eggs into Constantinople, where silk and linen fabrics were then being woven. We have ample proof that these countries had already acquired a high standard of decorative art by reference to ancient writers and Assyrian bas-reliefs, &c. These early silk and linen designs were chiefly lozenge or dice arrangements. Then developed designs of circular panels enclosing such figures as winged monsters, chariot races and animals back to back, each country having peculiar motifs of its own. We have several of these early fabrics dating from the 6th century onwards in the Victoria and Albert Museum, chiefly found in Egyptian tombs. The colours on many are still good, which speaks well of the dyes they used; several colours of weft were used often on a bright cherry, green, or gold ground. These circular panels were used for centuries but the detail drawing was gradually becoming more advanced. The first great change took place after the 9th century, when the Arabians conquered Persia, Syria, and the surrounding countries; they also moved westwards along the north of Africa and into Spain where they introduced silk weaving. Arabian influence can be traced in the art of all these countries after this date, and the early Spanish designs were purely Arabian. The silks of Constantinople were very popular at that time and during the 10th century designers introduced what is known as the "ogee" basis into their fabrics, a foundation on which many famous Italian designs were built. During the 12th century an important development took place when the Norman King of Sicily conquered Athens and brought a colony of Greek weavers to Palermo where they taught the Sicilians the art. It was not long before it was an important industry; the early designs were chiefly of Saracenic or Arabian character, but they developed a style of their own. The next step was the introduction of the industry into Italy near the end

of the 12th century and this was the beginning of a great age in textile achievement both from the artistic and the technical point of view. Lucca was the first and leading town during the 13th and 14th centuries and between these dates a complete change took place in the style of design. The circular panels and other symmetrical forms which had been so prominent for centuries were completely dropped and a freer style emerged. All the new designs suggested great activity; animals leaping, birds in full flight and trees bending give us some idea of the lively conditions of the industry. The draw loom was improved and textures became richer; metal threads were now being used. Venice, Florence, and Genoa gradually took the lead from Lucca and from these cities came the wonderful velvet brocades which are certainly among the richest of all works of art. Figured velvets were being woven during the 14th century and the early designs were similar to those of the damasks or brocades, but the artist found that the animal and other forms such as sun rays, &c., were not suitable for these new and luxurious fabrics. This brings us to the late Gothic style, probably the most majestic of all, the principal features being the bold treatment of the plant form—such as the vine or pomegranate motifs—and the wide bands often on the ogee basis. Italy remained the leading silk country during the 16th century, but the French were now making rapid strides and gradually taking the lead. In the Italian 16th century fabrics we find the pineapple introduced, also flower vases and generally more detail which gave a different distribution of figure. It is largely the well-balanced distribution of the figure in the Italian designs of the 16th and 17th centuries which makes them so suitable for modern fabrics. The later designs included imitations of the prevailing French styles which had become so popular.

The industry was really introduced into France during the latter part of the 15th century and followed closely on the Italian lines for a time, but during the 17th and 18th centuries the French produced original styles and gorgeous fabrics equal in workmanship to the famous Italian textures. The nature of the designs and colourings was much brighter and more elaborate than anything seen before. [*Louis XIII., XIV., XV., and XVI. styles were then described and samples shown.*] With the French Revolution came a distinct change in style; no ribbons, garlands, and sentimental love emblems were seen as in the previous modes, but a more severe type of ornament, arranged on symbolical lines, at the same time being majestic. After the downfall of Napoleon we find a gradual return to naturalistic drawings and colourings, but they never attained the same standard as the pre-Revolution styles. In the latter part of the 19th century came the Art Nouveau movement, a mode which has often been described as the "weird and fantastic"; orthodox traditions being completely disregarded.

Decorative silks were not being woven in England in large quantities before the arrival of the Hugenots from France near the end of the 17th century, but early in the 18th century, silk weaving became a most prosperous industry. Elaborate brocades and velvets were produced very similar in every respect to those of the Continent. During the century, however, English styles became distinct from the French and they are still very popular in all countries. The famous furniture and interior styles of Chippendale, Sheraton, and Adams had a great influence on the textiles, and we find a gradual change from the bold designs of the Early Georgian to the more delicate ones of the Adams' decoration. Just as the 18th century is referred to as the "Golden Age" in British decoration, so the 19th is just the reverse and we find that very few things of this period have much artistic merit. Early in the 19th century Jacquard and power looms were gradually taking a firm hold and designs were being produced in increased numbers but of inferior quality. The high class trade had almost vanished by the middle of the century and then came a revival largely inspired by the "Arts and Crafts" movement of which William Morris, Burne-Jones, and Walter Crane were leaders. A new interest was created in all forms of decorative art, and

when referring to the particular branch of velvets and brocades it is difficult to leave out the name of the late Mr. Benjamin Warner, whose energy and skill gradually brought the craft to life again. The modern style of decoration as we saw it at the International Exhibition in Paris last year caused a great amount of interest in the furnishing world for all the exhibits were original in design. I have a few drawings which will give you a better idea of the "New Style" than any remarks of mine. Having one or two designs of my own in the Exhibition I am not the proper person to express an opinion on the artistic merits of the various nationalities. I am certain of this, however, that so far as the textures or qualities were concerned the British exhibits were equal to anything on view. Whether there will be a great demand for the New Style remains to be seen, but at present the old designs to which I have referred are being produced in huge quantities on all types of fabrics. Many we see are crossbreds, part of an old design being used and modified to make a cloth suitable for the upholsterer who requires a design which will cut up without waste. I will close with a few remarks on the respective merits of power and hand loom production. There is no doubt that the power loom is making giant strides and producing a wonderful range of fabrics, such as damasks, tissues, and brocatelles, but there will always be a need for the hand loom when producing the richest class of goods. The power loom has advantages in allowing the designer to obtain many fancy effects through being able to lift a greater number of individual threads than the hand loom worker can lift, but against this must be set off the exquisite feel which is obtained by the hand loom weavers' personal control of every motion on the loom.

Discussion

Mr. E. Wigglesworth—From the samples that Mr. Woodman has shown this evening, it appears to me that even to-day we still have designers in England who can equal the work of those artists who produced fabrics when design had reached its highest standard. I would like to ask Mr. Woodman if in his opinion sufficient attention is now being paid to the training of designers in period work. The hand loom, of which most of the fabrics shown here to-night are products, still seems to be a necessity where fine work is demanded. To-day in Ireland weavers find that for the finest grades of ladies' handkerchiefs there is nothing like the hand loom. Is it possible to secure any training in hand loom weaving to-day, and do the big distributors give any encouragement to hand-woven fabrics ?

Capt. S. E. J. Brady—It is very satisfying to see such fabrics as are displayed to-night and to know that they have been woven in an English factory. Were these cloths (pointing to a Louis Seize tissue) woven in 28 or 50 inch widths ?

Mr. Woodman—These are all 50 inch cloths. The design repeats four times across the width.

Capt. Brady—Can you manufacture these on the power loom ?

Mr. Woodman—Yes ; but there is a limit to the number of ends to the inch we can use successfully on the power loom. To reproduce that design on the power loom we should use less ends per inch, but a thicker warp.

Mr. E. Wigglesworth—What is the difference in cost ?

Mr. Woodman—Using less ends per inch I should imagine that this design (again referring to the Louis Seize) could be reproduced on the power loom at about 40% less than the hand loom cost. With the hand loom the weaver must study his fabric very carefully—the value drops immediately with any flaw. (Replying to Mr. Wigglesworth, Mr. Woodman said)—Conditions are very different to-day from what they were at the time many of these famous designs were produced; in the old days members of the aristocracy were the only people who possessed decorative fabrics. Weaving was not a factory craft. The designer could concentrate on productions without much regard to cost and size, &c. To-day, although there is more demand for originality than ever, the manufacturer and designer usually have to consider the usefulness of fabric and cost of

production, which means that the finest designs, from a purely artistic point of view, are not always the best sellers. It must be remembered that many fabrics of this type are to be used in the upholstery trade, and in consequence one must always bear in mind the question of "cutting-up."

Capt. Brady—All the designs you are showing are floral or figured. Is not the modern tendency towards geometric design ?

Mr. Woodman—We do produce a few geometrical designs.

Capt. Brady—With small repeat ?

Mr. Woodman—Yes.

Mr. D. Anthony-Langsdale—If we were to get away from the floral or natural type of design in this class of fabric, it would be very interesting to see what would replace it.

Mr. A. B. Shearer—I would like to call attention to the effect that religion has had upon design. Mohammed taught his followers that it was impious to copy the designs of the Almighty and as a result the Arabic and Saracen designers produced patterns in geometric forms. The influence of this can be noted in the later Gothic type. There is a good deal of misunderstanding as to the capabilities of the power loom. The power loom can do anything which the hand loom can do, and a great deal more. The hand loom cannot lift the number of ends that the power loom can lift—I know several power looms using 5,000 hooks; could the hand loom do that ? I have operated power looms using 400 ends per inch, and successfully, and I contend that the power loom on account of the greater number of ends which can be lifted, gives the designer more scope.

Mr. Woodman—Efficiency of output or effectiveness of treatment must not be regarded as the artistic side of weaving. The old draw loom produced fabrics quite equal in quality from the artistic point of view to the finest modern power loom. We ourselves are continually experimenting with our power looms, but up to the present we find that the personal touch which characterises hand loom weaving cannot be obtained on the power loom. It does not necessarily follow that two fabrics each of 400 ends per inch, the one woven in a power loom, and the other in a hand loom, will have the same delicacy of handle or appearance. Otherwise nobody would employ hand looms. We often have orders for certain tissues with peculiar effects, and we find that these effects are more easily obtained on the hand loom.

Mr. Shearer—When one considers the full potentiality of the modern power loom, there seems to be some possibility of producing completely new designs. The invention of the jacquard removed the restrictions of the draw loom, and the modern power loom should to a certain extent remove the restriction of the hand jacquard.

Mr. Woodman—I quite agree.

Mr. E. B. Fry—Mr. Shearer has mentioned 5,000 hooks (here Mr. Shearer interrupted—"5,000 or more"), I have seen looms using six jacquards with 1,200 hooks each, i.e., 7,200 hooks. I could imitate that Louis XVI. fabric on a power loom and you could not tell the difference.

Mr. Shearer—Taste is improving, especially women's taste. Look at the shops now and compare them with 20 years ago—the quality and design of fabrics displayed has improved to a remarkable degree.

Mr. Fry—Were not the early designs chiefly used for tapestries ?

Mr. Woodman—Yes, it was not until about the late Gothic period, that is the 15th century, that furnishing and dress fabrics parted ways. Previous to that time all figured silk designs were used for the dual purpose.

Mr. Anthony-Langsdale—I have great pleasure in moving a vote of thanks to Mr. Woodman for his very excellent paper. I have always understood that the earliest forms of design, at any rate as far as Egyptian tapestries are concerned, made use of allegorical subjects such as chariot races, or games of quoits. Is it not possible that use might be made to-day of allegorical designs ?

The vote of thanks to Mr. Woodman was carried by acclamation.

DESIGN AND STRUCTURE OF WOVEN FABRICS

THE TEXTILE INSTITUTE'S "CROMPTON" PRIZES FOR 1926

ALSO SPECIAL PRIZE AWARDS FOR FABRICS AND FOR FANCY YARNS

The Committee of the Textile Institute concerned with the adjudication of the specimens submitted for the current year's competitions announce awards as under—

WOVEN FABRICS

First Prize (Certificate and £35)—L. B. Sutcliffe (Bradford Technical College).

Second Prize (Certificate and £25)—E. J. Poole (Bradford Technical College).

Third Prize (Certificate and £15)—M. Taylor (Salford Royal Technical College).

Prizes of £5 each—Miss G. Holsgrove (Burnley Technical College); H. Ayrton (Clitheroe Technical School); R. Ingham (Burnley Technical College); W. Taylor (Burnley Technical College); A. Mutton (Burnley Technical College); J. Walton (Nelson Technical School).

NOVEL WOVEN FABRIC

Special Prize of £10 for specimen of cloth of original and novel texture—L. B. Sutcliffe (Bradford Technical College).

WOVEN FABRIC (SPECIAL STUDENTS)

Special Prize of £5 for specimen of cloth submitted by a candidate for Honours Grade (Section A) of the City and Guilds of London Institute in the same year—R. Jackson (Nelson Technical School).

YARNS

Prizes of £5 each—C. Sumner (Blackburn Technical College); A. Eccleston (Blackburn Technical College); J. Woods (Blackburn Technical College).

The Committee report that although the number of participants in the principal competition is slightly lower than in some previous years, yet the general character of the specimens submitted is exceedingly good. The competitions are limited to advanced students, and fluctuations in numbers of contributors is therefore only likely to take place within very narrow margins. Advance in achievement by competitors is a consideration of far greater importance than advance in mere numbers of competitors. The specimens for this year represent a considerable stride forward. Improvements in many directions are effected, and especially gratifying is the more widespread tendency to aim at the retention of commercial value along with attractive structure and design. In some instances, however, competitors might have given greater consideration to tendencies indicated by current retail trading activities. Watchfulness in regard to vogue possibilities is always of extreme importance.

There were 10 contributors to the principal competition; 7 competitors for the special prize of £10; 3 for the prize of £5 for special students; and 3 for the yarns competitions. Two additional awards of £5 were made in the principal competition.

The prizes for yarns form a new feature of Institute competitions, due to the offer of Messrs. R. Greg & Co. Ltd., South Reddish, Stockport, who have kindly provided the necessary prize money for a period of three years. Notwithstanding the submission of but three sets of yarns, the Committee welcomes the commencement made. The specimens indicated that the general principles to be pursued are well understood. Ingenuity in colouring and twist is shown by all, though generally the results show a tendency to overreach in the matter

of cost of production. A general omission from details is the finished count of the yarn—a most important factor in relation to price.

In regard to next year's competitions, the Committee, as in previous years, have carefully revised the conditions. It is recognised that change is more or less inevitable from time to time if progress is to be maintained. Due to representations made to the Committee at a recent conference, somewhat drastic alterations have been effected in the conditions set out in the prospectus for 1927, and both students and teachers are urged to study the revised conditions and to assist as far as ever possible in promoting the success of the scheme. The prizes are again extended, and the Committee earnestly hopes that more individual firms will come forward and offer prizes, thus maintaining steady development of the scheme of competitions as a whole.

PRESENTATION OF PRIZES AND CERTIFICATES

Address by Mr. James Morton, of Carlisle

The presentation of prizes and certificates, in accordance with the foregoing list of awards, took place at the Institute, Manchester, on Saturday, 11th December. Mr. Wm. Howarth, J.P. (President), occupied the chair, supported by Mr. John Crompton (Chairman of Council), Mr. H. P. Greg (Vice-President), and Mr. J. D. Athey (General Secretary). Mr. James Morton (Carlisle) kindly attended and presented the prizes on behalf of the Institute. There was a large attendance of representatives of the Institute, and of numerous technical institutions, whilst students and others interested in the competitions attended from various textile centres. The exhibits were effectively displayed, and the availability of draping specimens of a number of the competitive fabrics added greatly to the interest of the display. The President welcomed the visitors and called upon Mr. Morton to distribute the prizes and, subsequently, a hearty vote of thanks was accorded Mr. Morton and the President, on the motion of Mr. Crompton, seconded by Mr. Greg. Incidentally, Mr. Crompton stated that the Competitions Committee would be pleased to consider special effort in regard to furnishing fabrics, Mr. Morton having expressed preparedness to help, if possible, in this connection. At the close of the presentation proceedings, afternoon tea was served in the Institute Council Room.

In presenting the prizes, Mr. Morton delivered a highly interesting address, as follows—

THE NEXT FORWARD STEP IN OUR TEXTILE INDUSTRY

By Mr. James Morton (Carlisle)

I must first of all thank your Committee for inviting one from the North into this atmosphere of young weavers. I am sorry to say it is now difficult to find such gatherings in Scotland. In former days, Glasgow and Paisley were weaving centres second to none in the world, but a generation or two ago young men seemed to forsake weaving as a vocation, with the result that a great deal of the special work formerly done there gravitated to Lancashire. Many young folks, perhaps, did not look upon weaving as an important enough industry and were attracted by newer industries more talked of, such as shipbuilding, engineering, electrical work, and the like. So, in case there should be any feeling among the young folks here that textiles and weaving are not worthy of their best brains, it may be useful to take stock of ourselves a little, to see what our industry embraces, the elements that go to the making of it, and the wonderful nature of the tools at our disposal. We are so familiar with them and we take everything so much for granted, that, like the old mystic "Snarley Bob," in L. P. Jacks' "Mad Shepherds," it is good sometimes to get out of our own globe and see our earth from outside—from another planet.

Now, what do we find to be the essential tools of the weaver, and what part and importance do they seem to play in the world's economy? The first, of

course, is fibres—the basis of all textile structure—cotton, linen, wool, silk, and its young, bright, synthetic sister. Do we quite realise what very varied activities these create ? In cotton, can we picture those scores of thousands of growers in the sunny southern lands of America, in Egypt, and elsewhere—the planting, the growing, the picking, the packing, the baling, the shipping overseas, and all the variety of life that these involve ? In wool, can we think of the breeding of the sheep, the pasturing in home, colonial, and other lands, from Australia to the high tablelands of Peru, the shearing, and all the teeming agricultural activities till the wool is baled, shipped, and landed at our various docks ? Can we follow the mysterious culture of the silkworm and its cocoons of silk under varying conditions of life from China, through India, right west to Italy and Southern France ? And, in another direction, can we realise the marvellous industry by which chemical and engineering skill have at last evolved for us a fibre brighter even than silk itself, though not so soft and kindly ? Then, on top of all that growing and garnering from the world's end, there is the varied manipulation of all these fibres—the sorting, the spinning, doubling, and twisting into all sorts of forms and sizes by thousands of spinners with their millions of whirling spindles. And all for what ? What have all those varied and far-spread activities been preparing for ? What for but to provide us weavers with the first of our tools—the raw, uncoloured yarn for the warp and woof of our web. Does it not make us feel just a little bit important to have such manifold servants at our call ?

But all these activities went to produce only the first of our tools—our fibres. The fibres provide only the structure of our cloth. It is colour that makes them speak, and that is our second essential tool. We have all heard a great deal in recent years of the development of chemistry, of the early discovery of Perkin's Mauve, of the great chemical factories that grew up in Germany as a result of this and similar discoveries; of the more recent developments in our own country and America—vast numbers of young men graduating at Universities and entering chemical factories, gigantic works, and combines, running into many millions sterling, and engaging the best brains of chemical science. And all, again, for what ? Very largely that they may provide dyes to colour the warps and wefts of the weaver. It is a rather staggering thought—this enormous scientific activity and ingenuity just to provide us with this second tool for our work. Engineering supplies us with our third tool, namely, the Mechanics of the Loom itself—a science which has developed as wonderfully as any already named, and which I scarcely need enlarge upon in a meeting of weavers.

I want to impress upon this meeting of young weavers the reality and the significance of this vast service that has thus been put at the disposal of our trade—this world-wide activity in science and commerce, all for the one specific purpose of equipping us with the tools of our industry. For these tools, we must remember, are incomparably more efficient and more valuable than any that have been available to weavers in the past. Fibres and yarns are more plentiful, more varied and more beautiful than have ever been produced at any period in the world's history; colours and dyes are in greater variety, more plentiful, and incomparably faster to all tests than in any previous age; and the mechanism of production puts opportunities to-day in the hands of the weaver that our grandfathers never even dreamt of. Botany, biology, chemistry, physics, and engineering have all so collaborated for our service that we are equipped as no other weavers in any age.

Now, how does it all strike us ? It certainly must impress us beyond any doubt with the vast importance that is attached to our craft in the world's economics, and the question we must ask ourselves is—How have we used these new and wonderful opportunities ? For, be it remembered, without a weaver, without the master weaver to direct, not one of these tools would be of the slightest practical value. Have we risen to our occasion ?

Suppose, like Snarley Bob, we creep again outside our globe and try to get a more comprehensive view of our own specific trade. It will be seen, I think,

that it divides itself into two broad divisions—two almost distinct grades of work. There is, first, the making of cloth that may be called a purely utility article—cloth that will hold together and wear, is wanted at the lowest possible price at which it can be made to serve its purpose, and, in many cases, is the raw material for other trades. There is, secondly, cloth with some form of decorative value—cloth that besides serving a more or less useful purpose has as an essential feature some æsthetic or decorative quality.

In the first section, I think we have reason to congratulate ourselves that the weaver has risen valiantly to the occasion. He has manipulated his new tools to such purpose that he has galloped abreast with the services of all the other sciences, and it may be said that, in this section, Lancashire led the world in the race. Why, I suppose that a score of spinners and weavers to-day will produce as much cloth as did the whole of Lancashire a hundred years ago, and one mill in Lancashire and Yorkshire will produce as much cotton and woollen cloth respectively as did the whole country at the beginning of the last century. Not only so, but, in the facile handling of these new tools, especially in the earlier period of the discoveries, this country so made good her opportunities that she was practically the weaving shop for the rest of the world. It was a wonderful achievement, and brought untold wealth and prosperity to these islands, and to no part more so than to the county of Lancashire.

Now, what about the other section of our craft—the decorative, which must always be much the more interesting for the real weaver? How did it fare through these hectic times? It is very difficult to have two really live and driving enthusiasms at one time, and I think it will be admitted that the real enthusiasm in the early generations of mechanical weaving in this country—and perhaps I may be allowed to say of Lancashire in particular—was concentrated on the mechanism of production, of mass production for world markets of more or less purely utility types. The novelty of the mechanism was so interesting and fascinating. It was like the interest we feel in our new motor cars which we hoped would carry us into all kinds of enjoyable natural scenery. We get so wholly absorbed in the pure mechanism and speed of the car that angels might be passing and we should never see them! That was all very natural and understandable, and, at first probably inevitable. But it had its dangers and limitations, and was bound to have its reaction. For other countries soon coveted our machines, and prepared to make their own requirements. Tariffs rose up to help, with the result that we have now reached a stage when many of the countries that once kept Lancashire busy are now making for themselves, and Lancashire is being faced with a problem new in her textile history. It is a stage that has been foreseen for many years, but the economics of the war have done much to hasten it. With the needs of our more complicated civilisation, with the wages, rates, and taxes inseparable from our higher standard of living, and expensive municipal and Government services, it is impossible that we in this country will ever be able to compete with many of the less advanced peoples in services which they can equally render. This means, without any doubt, a gradual shrinking of the trade in this country for purely utility merchandise. And the great problem for us, to-day, as textile manufacturers—Lancashire and others—is whether we are ready for the next forward step. This step undoubtedly lies in the direction of what is known as the Decorative Fabrics—more difficult to create, but intensely more interesting—fabrics that depend for their value and merit, not purely on their mechanical construction, or their cheapness, but on the skill and interest in their construction, the beauty of their design, and the sympathetic manipulation of their colour effects. It seems to me that we have arrived at what may be the testing time for our craft, and it is this phase that gives value to such projects as we are met to aid to-day. It was this aspect of things I am sure that prompted Mr. Crompton to inaugurate these competitions as notes of encouragement in the new direction.

It is a big problem how best to stimulate interest and develop taste for the finer side of decorative textiles, how best to develop these faculties so that they will translate themselves into the work of everyday life. We have had many movements in the form of art classes and museums, but want of a driving necessity has perhaps made those less real and vital than they otherwise would be. But there is no mother like necessity, and I have great hopes that when it once gets into the minds of the weavers of this country that a new departure is vital to our existence we shall rise to the occasion. I should like to impress this upon you young weavers with all the force I have. In our country, we have in the future to depend more and more on individual, high-quality work; others can do the simple and more mechanical work. Let us seek out things to do that are difficult. That is where there is lots of room, and where you can least be followed. When all the world is running away with your mechanical, monotonous work, get on to something better, something that is of greater interest in the making and that can command its own market. We must weave thought and interest into our fabrics. It is for this that the world will look to us more and more, and this we must be prepared to give. If the people of our country are educated to want and to enjoy a higher standard of living, it must be made evident in our products if the world is to pay the price that our higher wages and higher costs entail. And let us never fear that there will be a market for the best that we can think or do. Even in this poorer world, there is an ever-increasing number of people who can appreciate things of individual character and beauty. In spite of high tariffs in America, for example, there is an ever-increasing demand for work of that individual character. It is a type of work that conditions of life in America make difficult of production in their own country, while there is an ever-increasing number of educated people who are able to appreciate those higher individual products, and who have the wherewithal to pay for them. In our own country, also, there is an ever-growing public to welcome products possessed of personality and individual character, and, as things settle down, and other countries of the world again get into regular production, wealth will become more general and the demand for these higher class fabrics will be ever on the increase. To meet this greater demand for individual work may mean a considerable recasting of our industry; in many cases it will involve substitution, other types of looms, and it will mean a new outlook on the part of the weaver and the manufacturer. There may be less bulk, but not less value nor necessarily less profit. It need not mean less labour, while that will be of a far more interesting and educated type.

And in this direction, surely, lies the great opportunity for those new tools already spoken of. It seems to me we shall only then be making worthy use of them. I often think of William Morris worrying over the fugitiveness of his dyes and sticking to his indigo as almost his one sheet anchor. How he would have revelled in the galaxy of fast colours that would now be at his command. If you young weavers want to get smitten with some of the enthusiasm of your craft, read the life story of William Morris and carry it into your everyday job. He was out of his time, but it is his keynote we want to catch now, even for the Lancashire looms. For it is just that livingness and freshness, and individuality, which he put into his fabrics and all his products, that the world will want from us. Someone said, in describing another of his crafts, that "Morris began to stain his wallpapers with poetry." It is something of that we want and that will be more and more expected of us by the markets of the world. To equip ourselves, we want to dip into the finest old products of the past, not to copy or imitate, for those were produced by methods and under conditions that are no longer ours. But we want to feel what there is in them that has made them live and that make them thrill us to-day like an old song. We are too afraid of ourselves in these times, too self-conscious, too timid of putting anything of our real selves into the things we design or do. Yet, that is just the secret of these fine old masterpieces; they are so spontaneous and unconscious. Look at some of the old Peruvian

textiles, for example, the fun and drollery in the figures, and the superb colouring. What fun the old weavers must have had in making them. That fun is in them for us to enjoy to-day. Can we catch something of their spirit ? To-day "the world is so full of a number of things," of such infinite variety and interest on which we all have thoughts of our own. Why should not those find expression in the designs and colourings of our fabrics, and so make them modern living things ? Why should we be content to continue making copies of old documents that have now lost their meaning for us, when there is so much to say and portray about our own times and surroundings ? We are apt to take our art exercises far too seriously, to sweat ourselves into impossible attitudes to find something that does not or never did exist, and that can make no living appeal. We need only to be natural and spontaneous, to express something of what we feel of the beauty and interest in the life and living things around us as did those old craftsmen who carved those simple, roadside flowers and fruits and those interesting animals and grinning gargoyles that make our ancient buildings live and speak to us to-day.

"We waste endless pains," says Anatole France, referring to some modern artists, "in copying old armour and old oak chests. The artists of olden days never troubled their heads with such like pedantry. They gave the heroes of legend or history the costume and appearance of their own contemporaries. Thus, they depicted for us in natural colours their soul and their century. Can an artist do better ? Each of their personages was someone of their own circle, and these figures, living pictures of their life and thought, remain for ever touching. They bear witness to future times of sentiments and emotions actually experienced. . . . It is the artist's part to love life and show us it is beautiful."

But I can well imagine someone saying that these things surely belong to the High or Higher Arts and are outside the domain of mere textiles. Just so ! And that is where we are so apt to misunderstand and under-estimate both ourselves and our craft. For art is really one. We started on this little survey, this little stocktaking of ourselves, with the object of finding out what place and relative importance our industry bore in the world economics—how we stood in relation to the sciences and other new activities.

Now, I want to say something rather under one's breath, as it were, in this meeting of purely textile friends. I have had occasion during the past dozen years to be largely immersed in the work of chemists, in the developing of dyes and the application of them to the various fibres. In that way, I have had to meet and work much with chemists, from the highest to the ordinary working staffs. And—let us whisper very quietly—I feel that they are ahead of us in their craft, that the chemical and mechanical achievements that have been put at our disposal have outrun the uses that we, as weavers, have so far been able to put them to. We have been provided by science with the most wonderful tools and materials, but that is not enough. We must add to them that alchemy which alone can make them into things of living beauty. We must handle them and fondle them and blend them into a harmony that can only come from the spirit of the true artist. That is the real function of the master weaver, and the spirit in which I commend you young weavers to take up your task. It is the master tool of our craft—a live sense and instinct for the beautiful and the faculty to translate that into the everyday work of our hands. If we can catch that spirit and hold it, the future will still be ours, and, as our mechanical bulk business inevitably slips from us, we shall be making for ourselves new markets that will be surer and more permanent than we have ever had before. And we shall be doing work that will not only give lasting pleasure to the users of our products but that will bring ever-increasing joy to ourselves in the doing. And this is no fancy, but is the practical advice of one who has had 40 years' experience and knows the truth of it all so well. So good luck to your fishing !

NOTES AND NOTICES

Meeting of Institute Council

At the December meeting of the Council of the Institute, the proceedings were less protracted than usual. It was reported that satisfactory progress had already been made with respect to the programme of papers to be presented at the next Annual Conference, at Bolton, during next Whit-week. The President (Mr. Wm. Howarth) is taking a keen personal interest in the fixture and the arrangements. An excellent programme is contemplated. It was decided to record on the minutes an expression of the Council's keen regret on account of the death of Lord Emmott. Minutes of various Committees were accepted, and, arising out of the matter of library accommodation at the Institute premises, the question as to whether any rearrangement of the premises could be advantageously carried out was referred to the Finance Committee, with power to add. At the conclusion of the meeting the Chairman (Mr. John Crompton) wished the President and members a happy Christmas.

The Institute's Invested Funds

Mr. T. Fletcher Robinson, Hon. Treasurer of the Institute, emphasises the importance of the note which appeared in last issue in reference to the Foundation Fund, and to the adoption by the Council of recommendations of the Finance Committee in favour of extension of the application of the principle of investment of funds. In so doing, Mr. Robinson points out that the Foundation Fund, started by the late Sir William Mather during his presidency, and also given special impetus by the efforts of Sir Frank Warner, in his period of presidential office, has already proved of enormous benefit. The Institute's work and its developments could not possibly have been maintained in the absence of supplementary income from investments. The late Sir William Mather's judgment as to the future financial needs of the Institute was characteristically far-sighted. Investment of funds and the application of annual revenue by way of interest may represent movement which is slow, but it is sure and permanent. The Institute is yet young in years, and no safer policy than investment of any available funds can be pursued. The Institute's great work of publication of scientific and technical literature represents an annual expenditure which has advanced enormously in recent years. The volume of matter for publication continues to increase, and it is therefore quite appropriate that the keeping alive of the interest in our Foundation Fund should have been specially urged. The original project aimed at a fund of £50,000; we have reached the stage of £12,000, in round figures. Usually donations have ranged between £1,000 and £50, but even smaller sums would be heartily welcomed. It has been decided that, for the future, all subscriptions received in respect of Life Membership of the Institute shall be invested. A single membership subscription of not less than twenty guineas covers the financial obligation for Life Membership, and henceforward members who decide to seek permanent membership by payment of the amount stated, or over, will at least have the satisfaction of knowing that the contribution involved will help towards the permanent upbuilding of the Institute.

Meetings at Institute Headquarters

Arrangements have been concluded for the delivery of a Chadwick Trust Lecture at the Institute in February next. Provisionally the event is fixed to take place at 3.45 p.m. on Friday, 25th February, under the auspices of our Lancashire Section. The Chadwick Trustees have notified that Dr. C. S. Myers,

Director of the National Institute of Industrial Psychology, will contribute the lecture, and the meeting will be open to the public. Another fixture of particular interest is provisionally arranged for Friday, 11th February, at the Institute, when it is expected that Professor Paul Krais, of Dresden, will attend and speak on the subject of textile research in Germany. Professor Krais will be at Bradford on the 10th February, when he is to address a meeting of the Society of Dyers and Colourists, and it is anticipated he will come along to Manchester the following day.

A Comparison of Juvenile and Trained Judgments

On 11th November, Mr. Henry Binns, Chairman of the Yorkshire Section Committee of the Institute, addressed a meeting in the Great Northern Victoria Hotel, Bradford, and took as the basis of his remarks a paper contributed by him to this *Journal* (see pages T615–T641 of this issue), entitled "A Comparison Between the Judgments of Individuals Skilled in the Textile Trade and the Natural Judgments of Untrained Adults and Children." The contribution, said Mr. Binns, was a long one and he did not propose to read it, but to draw attention to its salient points and to some wall charts he had prepared of this and parallel investigations, which gave interesting and striking confirmation of his conclusions in respect to the basic factors of judgment and the influence of training thereon. Mr. Binns proceeded to outline his investigations and to describe the methods employed, and in conclusion answered several questions put from the audience. Mr. Thomas Boyce, Director of Education for Bradford, who presided, expressed the opinion that the application of psychology to industrial pursuits had entirely justified itself, particularly in the direction of the economy of human effort, the rate of output, and the selection of young people for special employment. A hearty vote of thanks to the lecturer terminated the proceedings.

Textile Institute Diplomas

Elections to Fellowships and Associateships of the Institute have been completed as follows, since the publication in November of the previous list—

FELLOWS

CRAIG, George Lorimer (Huddersfield)
HIGHLEY, Arnold (Bradford)
MARBLE, Edwin H. (Worcester, Mass., U.S.A.)

ASSOCIATES

BOLTON, Harold Samuel (London)
HARTLEY, James (Colne)
THREADGOULD, George Henry (Harwood)

Publications added to the Institute Library

October to December 1926

Books

Report of the Bombay Millowners' Association for the Year 1925.
Skinner's Cotton Trade Directory of the World, 1926-1927.
Annuaire Pratique des Industries Textiles Belges et du Vêtement, 1926.
Official American Textile Directory, 1926.
Express Metric Quotation Reckoner. J. G. Inglis.
Modern Industrial Tendencies. Sir Charles Macara.

Additions to Institute Membership

At the November meeting of the Council of the Institute, the following were elected to membership—W. C. Appleton, jun. (New England Sales Manager, Viscose Co.), 1017 Hospital Trust Building, Providence, R.I., U.S.A.; John Callander (Research Chemist), 1 Christie Street, Paisley, Scotland; Alfred Crickmore (Journalist and Editor), *Textile Mercury*, 20 Mount Street, Manchester; Andrew M. Donaldson (Jute Manufacturer), c/o Wm. Fergusson & Sons, Ltd., Dudhope Works, Dundee; Thomas Eastwood (Cotton Spinning and Weaving Manager), 20 Fenton Street, Rochdale; H. Gair Greg (Cotton Spinner and Doubler, Director), Lode Hill, Styal, Manchester; Arthur Hollas (Cotton Manufacturer), Heaton Grange, Bolton; Weston Howland (Assistant Treasurer, Cotton Manufacturing), c/o Warwick Mills, 49 Federal Street, Boston, Mass.,

U.S.A.; Leonard Kleeb, jun. (Manufacturing Hosiery), c/o Ipswich Mills, Ipswich, Mass., U.S.A.; James E. Lea (Manufacturer of Water and Coal Measuring Apparatus), c/o Lea Recorder Co. Ltd., 28 Deansgate, Manchester; Wilfrid L. Middleton (Manager of Card Cloth and Card Wire Works), c/o John Whiteley and Sons, Brunswick Mills, Halifax; Henry C. Olpin (Research Chemist), East Dene, Victoria Avenue, Borrowash, nr. Derby; William Peers (Retired Cotton Spinner and Manufacturer), Walshaw, nr. Bury; B. R. D. Sharp (Weaving Manager), 8 The Ives, Lidget Hill, Pudsey, Yorks; John Tattersall (Cotton Merchant), 206 Royal Exchange, Manchester; Frederick A. Tomlinson (Cotton Merchant &c.), Mayfield, Timperley, Altrincham; Cyril J. Whitelegg (Research Chemist), c/o J. Hardcastle & Co. Ltd., "Blackrock," Turton, nr. Bolton; Douglas G. Woolf (Associate Editor), *Textile World*, 334 Fourth Avenue, New York, N.Y., U.S.A.; William C. Evans (Wool Student), c/o Technical College, Bradford, Yorks; Allan Fouracre (Textile Tester), Long Lane, Harden, nr. Bingley, Yorks; W. L. Langton (Foreman Dyer), 131 Broomhill Road, Bulwell, Nottingham; Ernest Long (Cloth Salesman), 2 Langham Road, Seedley, Manchester.

At the December meeting of the Council, the following were elected to membership—M. V. Ashworth, c/o S. A. White Martins, Rua S. Pedro 67, Brazil (Foreign Representative, Textile Machinery); W. Bastard, Frog Island Mills, Leicester (Worsted Spinner); J. H. Brunskill, 42 Milton Street, Padiham (Power Loom Overlooker); F. W. Cannon, The Poplars, Sugden Street, Ashton-under-Lyne (Departmental Manager—Artificial Silk Importers); J. L. Crabtree, 2 Dunkirk Crescent, Warley Road, Halifax (Student); W. F. Edwards, 13 Browne's Terrace, Englewood, N.J., U.S.A. (Textile Chemist and Physicist); C. J. Elliott, 9 Sandringham Road, Ainsdale, Southport (Chief Electrical Engineer); Walter Garner, 312 Kensington Grove, Duckworth Lane, Bradford, Yorks. (Textile Research Chemist); Adam Glover, 55 Widdows Street, Leigh (Weaving Specialist to Courtaulds, Ltd.); Graham Hayes, John Berry & Sons, Ltd., Ashburton, S. Devon (Managing Director—Woollen Manufacture); H. S. Hele-Shaw, 64 Victoria Street, Westminster, London, S.W.1 (Emeritus Professor, Liverpool University); William Hilton, 193 Stamford Street, Brooks Bar, Manchester (Technical Inspector—Artificial Silk); Herbert Jones, Madura Mills, Madura, S. India (Cotton Carding and Spinning Master); R. O. Kohner, 11 Kirkham Road (Horton), Bradford, Yorks (Student of Textile Technology); William Lightbown, 124 Rochdale Old Road, Bury (Textile Engineer and Works Manager); R. B. Liley, "Glenholme," Westfield, Horbury, nr. Wakefield (Dyeing Supervisor and Manager of Shoddy and Rag Department); R. A. Lunn, No. 1 Ewangelicka, Lodz, Poland (Cotton Spinning Mill Manager); R. J. Mann, "Elandene," Cherry Tree Hill, Chaddesden, nr. Derby (Tinctorial Chemist, British Celanese, Ltd.); J. Martin, "Milnrow," 273 Blackpool Road, Deepdale, Preston (Head Textile Designer, Horrockses Crewdson & Co.); G. Osumi, 354 Shimmei, Komagome, Hongo, Tokyo, Japan (Professor of Tokyo Higher Technical School and Lecturer of Tokyo Higher Sericultural School); J. Preston, 47 Great Townley Street, Preston (Loom Overlooker and Teacher in Cotton Weaving, Textile Drawing, and Mechanics); Arthur Roberts, 41 Johnson Street, Tyldesley, nr. Manchester (Cotton Spinning, Head Tester, Howe Bridge Cotton Spinning Co. Ltd.); Norman A. Roberts, 73 Holborn Street, Mayfair Gardens, Rochdale (Secretary and Salesman—Cotton Spinning); C. D. Silas, c/o E. D. Sassoon and Co. Ltd., 73 Whitworth Street, Manchester (previously in charge of mills in India, now Head of Manchester Branch); Fred Smith, Cliff Mills Dyeworks, Bruntcliffe, nr. Leeds (Dyer); J. W. Sutcliffe, c/o James Stott, Ltd., Werneth Mills, Oldham (Business Manager); George D. Sutton, 62 Dorset Street, Haulgh, Bolton (Research Chemist); J. Rowland Wylde, "Mayfield," West Bollington, nr. Macclesfield (Apprentice Textile Engineer).

COMMUNICATIONS

Air Conditioning in Textile Mills

A review of a book with the above title, published by the Parks-Cramer Company, which appeared in our September issue, has resulted in the following correspondence passing between the Editor of the book and the reviewer. The correspondence appeared of such general interest that permission was sought from the two gentlemen concerned to publish their letters, which accordingly appear below.—Editor, *Journal of the Textile Institute*.

Letter from Mr. A. W. Thompson, Vice-President, Parks-Cramer Company, to Reviewer.

Dear Sir,—As I have read with considerably interest some of your valuable contributions to British and American magazines published for the textile trade, it occurred to me that the review of "Air Conditioning in Textile Mills," published in the September number of the *Journal of the Textile Institute* over the initials "S.A.S." was probably of your authorship. The complimentary nature of the first portion of the review is greatly appreciated, but I find myself somewhat puzzled by the exception taken to the remark on page 213—"The general laws relating to regain in textiles as deduced from the research of Hartshorne and his predecessors are now generally accepted . . . ." While believing that the statement in question was misinterpreted, the exception is perhaps justified by the existence of some work on the subject which has failed to reach me and in that case I hope you can, and will, give me some further light on such work as has been done under the auspices of the British Textile Research Associations, which is in direct opposition as is stated in the review. In explanation of the intended meaning of the statement in question, I would call attention to the fact that the statement itself refers specifically to the general laws relating to regain and hygroscopic equilibrium, which are summarised on pages 214 and 215 immediately following the statement, and if you will re-read the statement itself and the matter immediately following it to which the statement specifically refer, the original meaning of the statement will perhaps be more clear.

I am quite well aware that Mr. Shorter, in some of those articles which I have read, takes strong exception not only to Mr. Hartshorne's methods but to the correctness of certain portions of the latter's regain tables as published; but I am not aware that there exists any well-grounded dissent on the part of experts from the statements contained in paragraphs one to seven inclusive as printed on pages 214 and 215 in the publication under review. If any of these statements are seriously questioned by yourself or other experts, it is the writer's sincere desire to be fully informed on the subject. There is, of course, considerable controversy and sincere and honest difference of opinion between experts on such highly technical subjects. In compiling the handbook under review the present writer endeavoured throughout to avoid such controversial subjects and to treat the subject as a whole broadly and to avoid a too dogmatic and detailed treatment of the subject. I trust you will, therefore, understand that it is the writer's sincere desire to avoid any controversial discussion, seeking merely to correct his own impressions wherever they may be in error, and to add wherever he can to his general knowledge of the subject.

Because of the thorough and complimentary nature of your review of the Handbook, which is fully appreciated, I shall especially appreciate your reply.

Yours, &c.

Boston, Mass. (Signed) A. W. Thompson

14th October 1926.

Reply from Mr. S. A. Shorter to above letter.

Dear Sir,—I very much appreciate your interest in my review, and your desire to be fully informed on the subject of moisture regain. The latest work

on this subject is so recent that Chapter VII. of your book, though up-to-date at the time of writing, became out of date while going through the press. As you are probably aware, this sudden resuscitation of this important, but hitherto neglected, branch of research is due to the establishment of our textile Research Associations. A complete review of recent work in its relation to earlier researches is impossible in a letter, so that the best plan will be to consider the laws summarised on pages 214 and 215 of your book. Law I states that "in a given mass of material in hygroscopic equilibrium with the atmosphere to which it is exposed, the regain depends upon the humidity and temperature." This law is not true. It has been shown that the regain of cotton in an atmosphere of given humidity and temperature is greater when it attains equilibrium by gaining moisture[1].

Law II. is much too vague to deserve calling a "law" and too vague and non-commital to call for criticism.

Law III. is subject to the same criticism as Law I. The statement relating to the similar behaviour of "clean specimens of the same material" is certainly true for wool[2], and very probably true for other materials.

Law IV. does not deserve calling a "law."

Law V. states that "at a given relative humidity regain is less at high temperatures than at low." This is generally true, the only known exception being cotton at high temperatures and high humidities[3]. The quantitative forms of the above qualitative law, given in small type below it, are not true[3 and 4].

Law VI. is an alternative form of Law V. Law VII. is merely an approximate rule for mill practice.

The above brief criticism may be still further condensed by saying that the elimination of what is either immediately obvious or entirely non-committal from the seven laws leaves three definite statements, namely, Law I., the large type portion of Law V., and the small type of Law V., of which the first and last are untrue.

I am aware that the above criticism is merely destructive. In this case, however, constructive criticism would mean a re-writing of this section of your book, and this is a task of which you are just as capable as I am. If ever you think of doing this in a future edition, you will have the satisfaction of bringing the regain section up to the high standard set by the remainder of the book.

I append a bibliography of recent work on moisture regain.

Yours etc.,

(Signed) S. A. SHORTER.

REVIEWS

Cotton Spinning: Intermediate. By T. Thornley. Ernest Benn, Ltd., London (494 pp. and Index, 25s. net).

This book will be found to be a very useful addition to the Textile Institute and similar libraries. To the cotton spinning student and those engaged in the trade it fulfils the part of a text-book and also a book of reference. The price may, however, be detrimental to its popularity. This is a pity, as the subject is dealt with in a very practical manner, although in parts the subject matter is arranged rather disjointedly.

Chapter I. commences with a short statement of the principles involved in cotton spinning. This is very commendable, as the early treatment of the subject in this way adds interest to the non-student reader, while the student prefaces his study of the subject by obtaining a clear understanding of the whole principles involved, before studying their application in detail to the different

processes. The history in Chapter II. is very interesting, and the chronological table given must have entailed considerable research on the part of the author. The history and development dealt with at the commencement of each subsequent chapter of the respective machines used in the various processes is a new and welcome feature in the book. The process of mixing, opening, and scutching is very fully explained in Chapter III. The lecture diagrams are varied, and the descriptions of working parts excellent. The addition of diagrams and explanations of the present day requirements in such things as locking motions, lap guards, &c., together with useful prospective views, completes an excellent, full, and understandable description of the manipulation of the cotton in this process.

The four succeeding chapters deal with carding, combing, drawing, and fly frames in a similar manner. Here again are many very clear diagrams with full explanations as to practical working requirements of small but necessary details in such things as stripping combs and brushes, grinding rollers, &c., in cards, down to such simple parts as cap bars and traverse motions in fly frames. In fact the book excels in practical information, and it rightly includes such features as the duties of operatives under the Bolton Card Room List. The calculations on the respective machines at the end of each chapter are sufficient for all working changes. They are given with data from each respective machine and worked out in such a way as to be easily followed by the average student, and with few exceptions by the ordinary mill overlooker and operatives.

Chapters VIII. and IX. are devoted to spinning. This takes up over one-third of the book. The subject matter is very varied, and the practical knowledge gained from a careful study will repay perhaps the extra perusal necessary to get at the particular point sought. Had the arrangement of the matter in these two chapters been more methodical and in sequence the book would have gained unstinted praise. Having to collect from different parts of the same chapter points relative to the same part of the machine will no doubt reward the diligent, but the ordinary reader and student hopes to find all the data relating to the machine dealt with, collected, and arranged in sequence. Chapter X. deals with high-drafts. There are very good descriptions—supplemented by diagrams—given of the various patents. This is a very valuable and interesting addition to a phase of drafting which is at present engaging the attention of the most progressive minds in the trade. Practical results in high-draft yarn are such that the method must have a place in any text-book on cotton spinning. Chapters XI. and XII. give a varied assortment of recent examination papers appertaining to cotton spinning and its cognate subjects. Had the numerical answers been given where such are required, it would have added to its value as a text-book for the home or private student.

Altogether the book is a clear, full, and practical treatise on the middle processes in cotton spinning, and undoubtedly an advance on any of the author's previous works. It merits the reward of being in the hands of those engaged in the trade, and can be thoroughly recommended. J.H.

Skinner's Cotton Trade Directory of the World, 1926-1927. Thomas Skinner & Co., London (2,312 pp., 25s. net).

This is the fourth edition of what is now popularly known as "Skinner's," though this appellation will shortly have to be modified when the Wool Directory to be published by the same firm makes its appearance. Reviewing the 1925-1926 issue of this Directory, the writer characterised it as a herculean task to attempt to supply information in such detail of the cotton trade of the world. Such a description still holds good, and fresh credit must accrue to this firm for the manner in which the task has been undertaken and brought to fruition. Broadly speaking, the contents do not differ to any great extent in arrangement, but a fairly comprehensive addition has been made, giving particulars of cotton compresses and warehouses. A plea must once again be made for preserving the integrity of an editorial page. For example, cotton statistics commence on page 47, and do not reappear until three pages of advertisements have been passed. These statistics conclude most unexpectedly at the top of a left-hand page, and could quite easily be overlooked. The reviewer is, after twelve months, more firmly convinced than ever that an advertiser probably gets full value

for a special position facing editorial matter, but that an advertisement on an editorial page is merely a source of annoyance. It is to be noted that a slip supplied by the publishers points out that subscribers may have their copies of the Directory bound in sections if they so desire, and such a provision probably overcomes any individual objection to such a large volume. The book as a typographical and binding effort is praiseworthy, and a previous criticism that the guide tabs did not appear to be strong enough must be withdrawn, as a year's service has had no apparent effect on these conveniences. H.L.R.

Official American Textile Directory, 1926. Bragdon Lord & Nagle Co., New York (1,126 pp., 15s.).

This Directory is compiled by the *Textile World*, which in itself is adequate testimony to the excellence of the production. It contains reports of all the textile manufacturing establishments in the United States, Canada, and Mexico, together with a yarn trade index and lists of firms selling to or buying from textile mills. The first part consists of a list of textile establishments arranged alphabetically and geographically, and maps are supplied showing the location of textile districts. Part II. deals with raw materials, and in similar arrangement gives lists of merchants and brokers of cotton, silk, wool, waste, &c. In addition particulars are given of bleaching, dyeing, printing. and finishing concerns, and the book is completed by a very comprehensive index. At first sight it appears as if editorial matter were on white paper and advertising matter on pink paper, but this admirable idea is departed from in Part II., where coloured paper is used throughout. It would seem highly desirable to standardise the procedure in Part I. for the whole book. Of this, as of other directories, it is only possible to say either that the information supplied appears to be complete, or that in seeking certain information it has or has not been found. The Directory under notice certainly seems to fulfil the first condition, and so far has answered all demands under the second. It should meet the needs of anyone requiring a catalogue of the American textile industry. H.L.R.

Annuaire Pratique des Industries Textiles Belges at du Vêtement, 1926. Jules Bertrand and A. Laliere, Bruxelles (1,157 pp., 60 frs.).

Examination of the book under notice shows that it is divided into twenty sections each separated from its predecessor by a title page printed in six languages on strong coloured paper, and, of course, a list of the sections is provided at the beginning of the book, where also is to be found a list of Belgian towns and communes in alphabetical order indicating the provinces in which they are situated. In each section the information supplied is arranged under the names of the towns concerned alphabetically, and the whole range of information is complete. Section 10, dealing with clothing and accessories, is a deviation from the usual practice in compiling textile directories, and in this case, though it accounts for quite one-third of the total volume, does not result in an unwieldy book. Comment must also be made on the twelfth section, which gives particulars of Customs agents, ship brokers, and transport arrangements generally; this should be extremely useful. It is unusual to find particulars of makers of cardboard, office furniture, packing cases, paper, &c., in a directory of this kind, and the same remark applies to the next section (15), which gives a list of hotels, but the inclusion of these and particulars of calculations, imports, exports, and tariffs marks out this directory as one of extreme usefulness. H.L.R.

GENERAL ITEMS AND REPORTS

"Problems of Selling"

Miss Gladys Burlton, giving an address on the above subject before the Bradford Textile Society on Monday, 8th November, Mr. Arthur Hitt (President of the Society) being in the chair, said that salesmanship was more an art than a science, and it depended in the last resort upon personality, the right technique, and the ability to make use of science. Nevertheless the salesman must have at hand a great body of information ready for emergency; and not only was it necessary for that purpose, but it gave him a confidence that was felt rather than descried, and that was immediately recognised by the purchaser. It was a common saying that the customer was always right, and if the proverb were not taken too literally, it contained a great deal of truth. However excellent goods might be in the opinion of the manufacturer, if they were not excellent in the opinion of the public then they were not excellent Nowadays the public was more discriminating and more inquisitive in its shopping. Customers nowadays asked many questions—Will it wash ? Will it fade ? Will it stretch ? Will it shrink ? Will it wear ? How were these questions usually answered ? The manufacturers knew all about the subject, but were they successful in passing on their knowledge to the ordinary retail salesman and saleswoman ? She did not think so. There was an astonishing amount of ignorance, disastrous to the business concerned, on the part of the average salesman and saleswoman. There was, for instance, an astonishing lack of understanding about artificial silk. Such ignorance was really serious. It meant that there was a gap between the people who knew what was being produced and the people who had to sell it. The management of the firm was more to blame than anybody, because they should ensure that they had a really efficient and well-trained staff; but the idea of staff training was still looked upon as something rather freakish, and not a serious thing in building up a business. What was wanted as the next step in building up prosperity was to devote very serious attention indeed to the question of human efficiency in business. It had been overlooked astonishingly.

Mr. George Garnett said he thought a good deal that Miss Burlton had said would apply to the Bradford trade and any other trade. Staff training was supremely valuable to-day, and that statement was equally true whether one was dealing with retailing or with spinning, manufacturing, mending, or distribution. They could not expect to reach a better atmosphere in factories, and incidentally thereby a higher quality of production, unless they entertained a respect for those with whom they were daily associated, and went to the trouble of earning their confidence and helping to train them to do their work more perfectly. Time and money spent in educating people and getting them into a better mental attitude towards their work was money rightly spent; and far too little was spent on it, to the great loss of the trade.

Miss Burlton, replying to a question as to how the manufacturer could pass on his knowledge to the retailer, said more and more buyers were carefully reading the trade papers, and the manner in which advertising experts framed the advertisements meant that people were getting more definite information in that way. Many manufacturers also had got into the habit of attaching little leaflets or circulars to the goods they sent out; and that was an excellent method. With regard to staff training, a solution might be found if businesses would realise that they ought to spend a small percentage of their turnover—say one-fourth of 1%—on the training of their staff. The proper way was to have someone in the business whose whole mind was concentrated on the problem.

1—MILDEW IN COTTON GOODS
THE GROWTH OF MOULD FUNGI ON SIZING AND FINISHING MATERIALS

By LESLIE EWART MORRIS, B.A., B.Sc.

(British Cotton Industry Research Association.)

Summary

The paper deals with the relative liability of the more important sizing and finishing raw-materials to develop mildew damage. Flours, starches, dextrins, and gums were for the purpose of the investigation examined singly, while, further, the flours were only investigated in the unsteeped condition.

In the first place, the earlier literature on the subject of liability is reviewed, and a short account given of the origin and bio-chemical characters of certain of the substances investigated. The distinctions between cassava flour, cassava starch, and tapioca are specially pointed out.

The experiments are then described. These involved the cultivation of seven species of fungi, all obtained from cotton goods which had mildewed under ordinary trade conditions, upon size pastes and agar jellies.

For each of these fungi the rate of growth has been determined on the different sizing and finishing substances, and also the time taken to commence the production of spores for spreading the infection. This has resulted in the classification of the substances into groups according to their degree of liability to mildew.

I.—The dextrins and wheat, rice, and cassava flours, permit the most rapid growth and production of spores. Growth on the dextrins, however, tends to fall behind that on the flours after a time.

II.—An intermediate group is formed by wheat and maize starches, gum tragacanth, and soluble starch.

III.—The substances least liable to mildew are tapioca flour (cassava starch), sago, and farina. On these the fungi grew very slowly, and spore production was small. When treated with caustic soda, farina becomes quite unsuitable for the growth of mould fungi, as shown by the fact that only one species produced even slight growth on farina treated in this manner.

Finally, a brief interpretation of the results on bio-chemical grounds is advanced, the greater growth on flours than on starches being attributed to their nitrogenous and sugar content.

INTRODUCTION

In a previous paper, Bright, Morris, and Summers[2] have pointed out the complicated nature of the problem of mildew in cotton goods. The raw cotton itself may be infected and therefore a source of mildew trouble, or infection from the atmosphere and other sources may develop at some later stage between the conditioning of the yarn and the sale of the finished cloth. At one stage especially is mildew likely to occur, namely, after the warp has been sized. The reason for this is that, during sizing, the yarn is coated with substances such as flour and starch which are eminently suitable for nourishing mould fungi. Mildew spores—whether present originally in the raw cotton and yarn or occurring as infections subsequent to sizing—have therefore a favourable medium for development. Furthermore, in finishing

processes, it is customary to employ substances such as dextrin and vegetable gums, which may also serve as food materials for mould fungi and increase the risk of the appearance of mildew damage.

It becomes of importance therefore to know precisely the relation to fungus growth of all the substances used in sizing and finishing, so that, where possible, by judicious choice of constituents the danger of mildew attack may be minimised. This resolves itself into a study of the relative rates of growth and spore production of the different mould fungi which are likely to occur on the various materials used in the processes of sizing and finishing.

As far as sizing materials are concerned, certain opinions on the question of their liability to mildew are prevalent, but it is seldom clear whether these are based on actual experience or on the statements in technical handbooks. For example, it is often asserted that the starches obtained from the underground organs of plants, *e.g.*, roots or tubers, are less likely to become "mildewed" than those from aerial parts, such as stems or seeds. It is generally considered, too, that wheat flour is a much more suitable medium for fungus growth than farina or other starches, and on this account it is the practice to use an increased proportion of antiseptic with wheat flour.

In order to collect the existing information on the subject, a survey of the literature was necessary, and as no summary of it has been published previously, it was considered that this might with advantage form a section of the present paper.

Survey of the Literature

The technical handbooks usually present such views as have just been mentioned as mere statements of facts, but Davis, Dreyfus, and Holland[5] lay special emphasis on the part played by nitrogen content in producing differences in liability to develop mildew damage. They recommend the omission of wheat flour from size mixings (p. 57), "since . . . the starches generally . . . inasmuch as they only contain traces of nitrogenous matter produce a size less liable to mildew." In this connection they emphasise the importance of the estimation of nitrogenous substances in cloth analysis (*loc. cit.* p. 142), and state that "flour or flour paste is perhaps the soil of all others best adapted for mildew growths."

Farina is described by Davis and Dreyfus[5b] as a "non-nitrogenous material and but little liable to damage." Apart from this, and a suggestion by Bean[1] that the properties of farina depend on the character of the soil in which the potatoes are grown, there appears to be no mention of farina except in the tables of experimental results of Thomson[13], and Davis and Dreyfus[5] quoted below; but the general opinion of the industry is that a farina size is but little liable to damage by mildew. As will be seen later, this is confirmed by the present series of laboratory experiments.

The general properties only of rice flour and starch are given in the handbooks, but Thomson's table (see Table I.) shows that rice flour is but little less favourable than wheat flour as a medium for fungus growth, and a paste made of rice starch can be exposed to atmospheric infection twice as long as one of the flour before mould growths make their appearance.

Maize, or Indian corn-meal, is described by Davis, Dreyfus, and Holland (p. 71)[5] as not nearly so liable to mildew as wheat flour. Bean and Scarisbrick (p. 102)[1] say that a paste of maize starch will mildew much sooner than one of any other starch under the same conditions, and indicates that maize

flour is more liable to mildew than the starch, while Ermen[6] and Hadfield[8] attribute this greater tendency of maize starch to suffer from fungus attack to the presence of small agglomerations of starch and gluten. If these get on to the cloth, spots of mildew are liable to develop owing to the fact that gluten is a good fungus food, but it they are broken up by boiling such spots are less likely to occur.

Sago receives only general mention amongst the other starches, although opinion and experience in the industry show it to be but little liable to mildew. Direct experiments in this laboratory have confirmed this previously.[2]

Tapioca, according to Ermen[6] alone, is decidedly liable to give rise to mildew growths owing to the presence commonly of nitrogenous substances. It is frequently confused with cassava, which also has received scant attention from the authors of text books. In an anonymous paper in the *Bulletin of the Imperial Institute*[3] on the commercial development of this starch, it is, however, stated that "as a sizing material cassava *starch* would probably be found less liable than cereal flour to induce mildew in cotton goods on account of its much lower percentage of proteins."

Thomson[13] says that mildew does not grow either quickly or luxuriantly on dextrin, his experimental data for three kinds of farina dextrin appearing to support this statement.

With respect to gum tragacanth, Bean and Scarisbrick[1] mention the danger of the development of mildew on the small insoluble particles remaining if the gum is not sieved properly after steeping.

Experimental evidence on liability is advanced in only two cases. Thomson[13] determined "the lengths of time required for different starchy matters to allow the development of fungus life, after boiling each into a paste with water, in the proportion of 1 to 10." Davis, Dreyfus, and Holland[5] conducted a similar experiment and gave brief descriptions of the progress of the growth on their pastes when left in an exposed place. These results are combined in Table I. and further reference to the technique of the experiments is made below (p. T14).

Table I.
Time of Development of Mildew

	Thomson.	Davis, Dreyfus, and Holland.
Wheat flour	6 days (3 kinds)	9th day.
Rice flour	8 ,,	—
Maize starch	10 ,,	12–15th day.
Sago	10 ,,	12th ,,
Tapioca	10 ,,	—
Wheat starch	11 ,,	11th day.
Farina	11 ,,	16th ,,
Farina dextrin	16 ,, (3 kinds)	—
Rice starch	17 ,,	12–15th ,,

These results corroborate the general view that flours are more liable to mildew than starches, but disagree with Bean's statement[1] that maize starch will develop mildew much sooner than any of the others. Apart from this the two series of results differ in the detailed placing of the various starches.

In view of the paucity and conflicting character of the existing information, it seemed desirable to investigate the question of liability afresh, using

modern methods of mycological technique in place of the somewhat rough and ready procedure employed by earlier workers. Although the investigation is by no means completed, certain results have been reached which it would appear advantageous to communicate without delay.

THE PROPERTIES OF SIZING AND FINISHING SUBSTANCES

It may be advisable at this stage to give a few notes on the botanical and bio-chemical characters of some of the materials investigated in the present research, since a knowledge of these factors is essential to a full understanding of the relation of mildew growth to the substances concerned.

Botanical.

A description of the botanical origin and microscopical appearance of most of the flours, starches, and gums used as adhesives in sizing is given in so many technical handbooks that it need not be repeated here. Cassava, however, is not so familiar, and it may be as well to include a brief description of the various products of the plant, particularly as the nomenclature of these materials is considerably confused, the terms tapioca, tapioca flour, cassava, &c., being used apparently without discrimination. Restriction of these names to the sense in which they are used in the following account would eliminate this uncertainty.

The cassava plant[3] (known also as manioc) yields large, swollen root tubers, which occur in clusters at the base of the stem. In the preparation of cassava flour these roots are washed, peeled, and cut up. The pieces are then dried in the sun and pounded into a flour, which thus consists of all the constituents of the tubers, with the exception of the outside layers or rind. On the other hand, when cassava starch is being manufactured, the cleaned roots are grated to break up the cell walls and liberate the starch, which is collected in water and then dried in a vacuum drier or special kilns. If instead of drying in this manner the starch is heated on iron plates up to its gelatinisation temperature, the grains adhere together and the familiar granular lumps of tapioca are obtained.

Bio-Chemical.

The chemical composition of the materials used in sizing throws considerable light on the reasons for their different liability to develop mildew damage.

(i.) *Flours and Starches*—Whether obtained from seeds or other plant storage tissues, certain substances apart from pure starch are likely to be met with in commercial flours and starches, but to a less extent in the latter owing to the definite processes of separation which they undergo. Amongst these are various classes of proteins, such as albumins, which are soluble, and globulins, which are insoluble in water, and glutelins and gliadins, which are insoluble in water but soluble in dilute acid and alkali. Less complex nitrogenous substances, such as amides and amino-acids, may also be present, the relative proportions of these compounds varying to a wide extent. Non-nitrogenous substances such as fats and oils, mineral salts such as phosphates (which appear in most analyses as "ash"), and cellulose or "fibre" from cell wall residues are also likely to occur. Besides these impurities of botanical origin, the starches of commerce are also liable to be contaminated with acids and other substances employed during the processes of manufacture.

A selected number of analyses of flours and starches from various sources are collected in Table II.

Table II.

Percentage Composition of Flours and Starches

* Potassium phosphate.

The starch is the largest percentage component which can be utilised as food by fungi, but the variation in amount from one type of commercial flour or starch to another is not sufficient to cause any appreciable difference in the extent to which growth can occur on them. The pure starches are, however, not identical, such properties as the shape and size of the grain, the temperature of gelatinisation and the viscosity of the pastes produced with water exhibiting well-known divergencies. These characters though, are not such as to affect the nutrition of fungi, nor are the more obscure variations in physical and chemical constitution, except in the raw starch. The mildew problem of the cotton industry is therefore not concerned with such factors. According to Reichert[10] "boiled starches, whatever their source, are of equal digestibility" (*i.e.* by enzymes—which constitute the means of attack of fungi living on them), "yielding quantitatively and qualitatively the same saccharine products" (which determine fungal growth after the enzyme attack has been made). It is, then, to the impurities, which are certain to occur in the preparation of starch on a commercial scale, that one must look for the cause of differences in liability to develop mould growths.

Apart from moisture, the next most abundant constituent, and probably the most important from the present standpoint, is the nitrogenous matter, all of which is frequently included in the term "gluten." The quantity of this varies from over 10% in a hard wheat flour, through about 2% in some wheat starches, down to nothing in others. The variations which occur in the analyses of the same starch may be due to actual differences in the samples studied or partly to the divergent methods and classifications adopted by the different authors. The general relation of the existence of a higher percentage of gluten in the flours than in the starches is shown quite clearly, but, except possibly in the case of maize starch, the figures are not constant enough to place the starches themselves in anything like a definite order.

That differences with respect to gluten exist between hard and soft wheats is now recognised, but, in spite of the very large amount of research on the subject, it is not yet clear whether they are entirely or partly a matter of quantity or quality of gluten. The point of view seems recently to have shifted towards a recognition of the importance of quality, but results so far are not conclusive. The possibility of a greater amount of fungus growth occurring on the one than the other cannot therefore be usefully considered at present, although some experiments on both types of flour will be described in the present paper.

The presence of sugars is also likely to have a considerable influence, for owing to their solubility they are readily available for purposes of nutrition. Sugars may even be more important than some nitrogenous substances, for Chaudhuri[4] has recently found that the omission of maltose from a synthetic culture medium had a much greater effect in diminishing the growth of one species of fungus than the failure to supply asparagine in the same medium when maltose was present. Sugar occurs most abundantly in wheat and cassava, and to a less extent in maize and rice flours, but is absent from the starches owing to its removal by the washing process involved in their manufacture.

Except in dirty specimens which contain sand, the ash content of a starch represents the amount of contained salts. Of these, phosphates are always present, and Fouard (quoted by Stocks[12]) found the amount of phosphoric

acid in a starch containing 0·331% of ash to be 0·1915%. This amount may be too small to produce a nutrition effect of any magnitude, but as the phosphates affect the degree of acidity or alkalinity of the starch, they may in this manner alone exert some influence on fungal growth. The result of this will, however, vary considerably with the different species of fungi. Generally, the flours contain more ash than the starches, the figures for which show marked divergences.

Where data are given, fats also show a preponderance in the flours. Maize flour appears to be outstanding in this respect and may possibly contain enough fat to have an appreciable effect; the rest most probably do not.

The last constituent—variously described as bran, fibre, and cellulose—is not such as to affect the liability to mildew of the starch or flour concerned.

(ii.) *Soluble Starches*—These are prepared in a variety of ways, either by heat or by treatment with acids, alkalis, or oxidising agents such as chlorine, hypochlorites, or perborates. It is possible that the traces of these reagents left in as impurities may by themselves cause differences in the behaviour of the product. The starch itself has probably undergone a molecular change of the nature of depolymerisation and the size of the molecule may have been reduced,[12] but the alteration in solubility is more likely to be of importance. Dextrin is also frequently present and the mineral content is usually higher than in ordinary starch,[12] but unless the impurities are such as to cause a marked difference, a soluble starch should be intermediate in properties between its parent starch and the dextrin obtained from it.

(iii.) *Dextrins*—Dextrins are obtained from starches by acid, heat, or enzyme action, and so may be expected to vary considerably in their composition both as to the carbohydrates present and the residues of the reagents employed in their manufacture. These will affect the reaction of the product and appreciable differences may exist, for example, between an acid- and a diastase-dextrin; but variations in acidity do not affect all species of mould fungi in the same way. Some samples may still contain a proportion of unconverted starch or soluble starch, whereas in others the conversion will have proceeded so far that the sugars maltose and glucose may be present (see Table III.). These being soluble can be absorbed at once by mould fungi and growth may, at least, start off more rapidly on the dextrin than on the corresponding starch.

Table III.
Analyses of Dextrin—Percentages

	Dextrin	Glucose	Unaltered Starch &c.	Water	Mineral Matter	Authority
Province of Langa-salza Dextrin	72·45	8·77	13·14	5·64	—	Davis, Dreyfus, and Holland

Light British Gum	5·34	0·24	86·47	7·95	—	,, ,,
Brown Dextrin ...	63·60	7·67	14·50	14·23	—	,, ,,
Brown Commercial Dextrin	83·76	4·84	—	11·03	0·37	Bean and Scarisbrick

(iv.) *Gums*—The gums are not relatively simple carbohydrates, such as starches and dextrins, but partake of the nature of glucosides and acids.[7] On hydrolysis, they yield the sugars galactose and arabinose, which are suitable for fungal nutrition, but as the hydrolysis is not brought about as readily as that of dextrin to glucose, the gums are probably not as suitable substrata for mould growth as the dextrins.

Gum tragacanth consists of two parts. The first, which is made up of insoluble salts of the gum, produces a gel with water, whilst the second is composed of soluble salts of calcium, magnesium, and potassium. A certain amount of starch is present as an inclusion in remnants of cell tissue, and at times sugar may occur.[14] Traces of nitrogen are also present in the gum, the ash of which is largely chalk (50%), with a small amount (3%) of phosphates. Several analyses of gum tragacanth are recorded in Table IV.

Table IV.

Analyses of Gum Tragacanth—Percentages

Insoluble pectic substance	Soluble Gum	Starch and Cellulose	Ash	Water	Nitrogenous Bodies	Authority
60	8–10	5—6	3	20	Traces	Bean[1]
60—70	8–10	—	—	—	—	Haas and Hill[7] (p. 123)
—	—	—	3—5	About 17	·05	Stocks[12]
About 50	—	Starch, enough to blue iodine; cellulose, negligible	1·75—3·57	11—17	—	Wiesner[14] (Vol. I., p. 137)

THE SUBSTANCES INVESTIGATED

The materials studied in the present series of experiments, although not forming a complete set of the adhesives used in sizing and finishing, are none the less fairly representative. The remaining substances are being actively investigated and will be discussed in a later paper. The wheat flours were used in the unfermented state; the results of an investigation into the effects of steeping, which form a separate part of the general problem, are recorded in the succeeding memoir.

The following is a brief description of the materials employed; where not otherwise described they were ordinary commercial samples.

(1) *Strong (=hard) Wheat Flour*—A commercial mixture of Manitoba and Russian flours.

(2) *Weak (=soft) Wheat Flour*—A mixture of White Pacific, Chilian, and Australian flours.

(3) *Yeoman Wheat Flour*—Yeoman is an English wheat, bred originally at Cambridge by Professor Biffen. It combines the character possessed by Canadian hard wheats of producing a flour of good baking properties with the capacity of giving a yield per acre equal to that of the best English soft wheats.

(4) *Wheat Starch.*

(5) *Rice Flour.*

(6) *"Tapioca Flour"*—This sample was probably "Cassava starch," for it appeared to consist entirely of starch grains with no admixture of cell residues, and no proteins could be detected.

(7) *"Cassava"*—As this sample contained an appreciable quantity of cell residues, and also gave some of the protein reactions, it should be described as "Cassava flour."

(8) *Farina.*

(9) *Sago.*

(10, *a* and *b*) *Maize Starch*—from two sources.

(11, *a* and *b*) *Soluble Starch*—(*a*) This was a commercial sample found to contain both farina and maize starches. (*b*) Farina was the only starch in this specimen, which was prepared by Lintner's process.

(12, *a* and *b*) *Maize Dextrin*—(*a*) A white sample possessing an acid reaction. (*b*) The colour and smell of caramel indicated that this sample had been prepared by heat.

(13, *a*, *b*, and *c*) *Farina Dextrin*—(*a*) and (*b*) From different sources, but both white and acid. (*c*) Prepared in the laboratory by the action of diastase on a commercial farina.

(14) *Farina treated with* 1% *Caustic Soda*—Prepared according to Bean and Scarisbrick's method.[1]

(15) *Farina treated with* 1% *Caustic Soda and then Neutralised*—Sample 14 made neutral to litmus by the addition of dilute hydrochloric acid.

(16) *Gum Tragacanth.*

All the substances were examined qualitatively for proteins, sugars, and cell residues, to see that they agreed with the analyses given above in Tables II., III., and IV. Cell residues, proteins, starch, and dextrin were identified microchemically, and proteins and reducing sugars by macrochemical tests, namely, the xanthoproteic, biuret, and Millon's reactions, and the reduction of Fehling's solution. The results obtained are shown in Table V., in which + indicates a positive, ++ a very marked reaction, and failure to give the test at all.

THE EXPERIMENTAL INVESTIGATION

The Culture Media.

The materials were made up in two ways as media for the cultivation of fungi. For the first set a paste or pure size containing about 5 grams of the substance in about 100 cc. of size was used. With the exception of gum tragacanth, farina diastase dextrin, and the treated farina, this was prepared by grinding 5 grams of the substance into a thin paste with 25 cc. of cold tap water, and pouring this into 90 cc. of boiling water. The whole was then boiled gently for about five minutes, which treatment reduced its bulk. The farina diastase dextrin was prepared directly from a farina paste, made up as above, by adding diastase and keeping the temperature at 40° C. until a drop tested with iodine gave no trace of purple. The paste was then boiled up again to render the enzyme inactive.

The treated farina was prepared by heating 5 grms. of the starch with 115 cc. of 1% sodium hydroxide on a water bath for half an hour. One sample was used in this condition and the other was made neutral to litmus by the addition of dilute hydrochloric acid.

For the gum tragacanth media, 5 grms. were ground finely, steeped for a number of hours in 115 cc. of water, boiled, and used as in the case of the starches.

About 5 cc. of the pastes prepared in this way were poured while hot into test tubes, which were then plugged with cotton wool in the usual way for culture media and sterilised by heating in the autoclave at 15 lb. steam pressure for 20 minutes. This method gave a number of samples of starch paste, entirely free from living fungus spores or mycelium, which could be kept sterile or inoculated with pure cultures of any fungus at will.

For the second set of experiments, in which the growth rate of the fungi was studied, a solid medium was necessary, and this was obtained by the addition of agar-agar to the flour or starch paste. Agar-agar possesses very little, if any, nutritive value, and gives a transparent jelly with a neutral reaction. Three grms. of flour were ground with 15 cc. of cold water and poured into 75 cc. of boiling water and thoroughly stirred; 3 grms. of agar dissolved in 90 cc. of water and filtered, were poured while still hot into the flour paste, well mixed, and the whole then boiled for about five minutes. This medium was tubed and sterilised, and on cooling set to a stiff jelly. When required for use it was melted by heating on a water bath and poured into sterile Petri dishes, giving when cold a circular slab of jelly about 4 millimetres thick, the transparency of which varied with the starch used.

The Fungi.

Seven species of fungi were used as indicated in the table below.

Table VI.

Fungus	Description and Origin
1—*Penicillium* sp. 2 ...	A green species isolated from cops which had been stored in a box after conditioning.
2—*Penicillium* sp. 4 ...	Another green species from spotted printed calico returned from India.
3—*Aspergillus niger* ...	A black species from the same cops as No. 1.
4—*Aspergillus flavus* ...	A yellow-green species isolated from spots in Queensland raw cotton.
5—*Rhizopus arrhizus* ...	A whitish fungus from the same source as No. 4.
6—*Fusarium* sp.	A pink species also from the same source as No. 4.
7—*Cladosporium herbarum* ...	A greyish-green fungus obtained from coloured spots in West African raw cotton.

All of these were isolated from samples of material which had mildewed under ordinary industrial conditions, but the origin of the particular strains used does not represent the prevalence of these species. The third in the table, for example, has also been obtained from raw cotton of various types and from filled printed cloth, whilst the last species occurred in grey cloth woven from the same raw cotton, and again in several cases of warp mildewing. In short, the examination of numerous samples of cotton goods mildewed at all stages of manufacture shows that the fungi selected for this work are representative of the large number of species of the various groups of mould fungi which have been met with altogether.[2]

Plan of the Experiments.

Size Cultures—Pairs of tubes containing the starch pastes prepared as described above were inoculated with spores from pure cultures of the seven fungi just enumerated, and incubated at 25° C. (77° F.). They were examined periodically during one to three weeks, and the progress of growth observed. Records were kept of the first appearance of growth, and of the degree of spore production at any time, thus enabling comparisons on several different grounds to be made between the various materials as to their capacity for supporting the growth of mould fungi.

The classification of growth and sporing used for comparative purposes was into six groups, as follows—

0=No growth.
1=Growth, but no production of spores.
2=First signs of sporing.
3=Sporing definite but slight.
4=Sporing well advanced.
5=Sporing fully developed all over the surface.

Specimens of the original records arranged according to this scheme are given for *Aspergillus niger* and *Rhizopus arrhizus* in Table VII.

Table VII.
Classification of Growth in Size Cultures

Age in days	Wheat Flour			Rice Flour	Tapioca Flour	Sago II. 64	Maize Starch 52	Farina 82	Cassava 67	Soluable Starch 66
	Strong	Weak	Yeoman							
				Aspergillus niger						
4	1	0	1	1	0	0	0	0	2	1
6	4	3	5	3	0	0	0	1	5	2
7	5	5	5	3	2	0	0	1	5	3
8	5	5	5	4	2	3	2	1	5	3
9	5	5	5	4	2	3	3	1	5	4
				Rhizopus arrhizus						
2	4	3	3	2	0	0	0	0	3	1
3	4	5	5	4	0	0	1	0	5	4
4	5	5	5	5	0	0	3	0	5	4
5	5	5	5	5	1	0	4	0	5	4
8	5	5	5	5	3	2	4	2	5	4

It will be seen from this table that the classification of growth of either fungus varies from one material to another. For example, when the cultures were seven days old, *Aspergillus niger* had reached the groups 5, 1, and 0

on wheat flour, farina, and sago respectively. In words, it means that this fungus grew so quickly on wheat flour that it was sporing fully in seven days, by which time growth had only just started (Class 1) on farina, and had not yet appeared (Class 0) on sago. The larger the number, then, the greater the amount of growth which has taken place, and this applies for any fungus at any age. If, therefore, on a given day, the numbers of all the fungi are added together for each substance the resulting totals will give an indication of the amount of growth which has taken place, the larger the total the greater the growth, and therefore the greater the liability of the substance to develop mildew. This is the basis of the comparisons made later on from Tables X. (p. T15) and XIII. (p. T18), which thus take into account the growth of all the seven species at once.

Cultures on Agar Jelly—In the tube cultures just described, the growth of the fungi was restricted in area, the size of the colony being limited after the first day or two by the diameter of the culture tubes. The object of the second group of cultures on agar in Petri dishes was to study the capacity of fungi for spreading in a relatively unconfined space. Sets of three or four dishes, containing agar made up with the same sizing material, were inoculated centrally with spores of one fungus. When growth occurred the fungus was able to spread equally in all directions from the centre, and the average growth rate of the hyphæ in one sector being the same as that in any other, colonies which were approximately circular were produced (Plate I.). Two diameters (as nearly as possible at right angles) of the colony were measured, to the nearest millimetre, or half millimetre where the edge was exceptionally clearly defined, every few days, and the mean of the group of the three or four similar dishes calculated. By plotting the diameters for successive days, it can be seen that in most cases the growth rate is steady once the colony is well established. In a few instances, however, this is not so; the initial rate is not maintained and the graph shows a curve falling away from the straight line of the first few days. This means that with a given pair of substances growth may be more abundant on one at first, but eventually that on the other will overtake it. Apart from such cases, the graphs show clearly the differences between the growth rates on the various media.

The growth rates of four species of fungi were determined—

Penicillium 2, which gives colonies with a clearly defined edge, although its mycelium is colourless. On some media the reverse of the colonies, and even the medium itself, are coloured yellow. The growth of this species is relatively slow.

Aspergillus flavus grows more rapidly than *Penicillium* 2. Its mycelium is also colourless, but the edge of the colonies is distinct, although on some media it tends to become somewhat, though regularly, scolloped after several days growth.

Fusarium sp. grows much faster than the others and produces regular colonies, the edges of which are not easy to see on the more opaque media, but are usually quite even. A pinkish coloration in the medium is often developed.

Cladosporium herbarum has a coloured mycelium and produces clear slow-growing colonies.

To illustrate the consistency of the measurements, a specimen set of records for each fungus is given in the following table—

Table VIII.
Diameter of Colonies in Agar Cultures

1—*Penicillium* 2 on Sago.

Diameters to nearest 0·5 mm.

Age in days	Dish 1	Dish 2	Dish 3	Mean diameter	Increase per day
3	10·5×10·5	11·5×10	10·5×10·5	10·5	—
5	19 ×19·5	20 ×19	19·5×19	19·5	4·5
6	23·5×23·5	23 ×24	23 ×23·5	23·5	4·0
8	33 ×33	32 ×33	32·5×32·5	32·5	4·5
10	43 ×43	42 ×41	40 ×39	41·5	4·5
12	51 ×53	50 ×51	51 ×53	51·5	5·0
13	57 ×56	56 ×56	56 ×56	56	4·5

2—*Aspergillus flavus* on Farina.

Diameters to nearest 0·5 mm.

Age in days	Dish 1	Dish 2	Dish 3	Mean diameter	Increase per day
2	8 × 7	9 × 8	8× 9	8	—
3	14 ×13	14 ×15	14×14	14	6·0
4	20 ×20	21 ×22	20×21	20·5	6·5
5	26·5×26	27·5×27	27×26·5	27	6·5
6	33 ×33	34 ×34	33×33	33·5	6·5
9	51 ×50	51 ×51	50×49	50·5	5·5
10	56 ×58	58 ×57	54×54	56	5·5

3—*Fusarium* sp. on Yeoman Wheat Flour.

Diameters to nearest 1 mm.

Age in days	Dish 1	Dish 2	Dish 3	Mean diameter	Increase per day
3	31×32	31×29	31×31	31	—
4	44×43	42×42	42×45	43	12
5	57×57	57×57	56×58	57	14
6	72×72	71×71	71×71	71	14

4—*Cladosporium herbarum* on Lintner's Soluble Starch.

Diameters to nearest 1 mm.

Age in days	Dish 1	Dish 2	Dish 3	Dish 4	Mean diameter	Increase per day
3	10×10	11×11	11×11	11×11	11	—
5	20×19	20×20	20×20	20×19	20	4·5
7	28×28	28×28	29×28	28×28	28	4·0
10	40×40	41×41	40×41	41×41	41	4·5
12	48×48	49×49	48×49	48×48	48	3·5
14	54×54	55×55	55×55	55×55	55	3·5

The practical significance of the classifications obtained from these two types of culture should perhaps be pointed out here. The time which elapses before the observation of fungus growth—which on yarn and cloth is most frequently that of sporing—decides whether or not "mildew" will appear, for example during a week-end stoppage of the loom or during a period of storage of the cloth. The quantity of spores produced in a given time determines the amount of these which will be free to fill the air with infecting material on being disturbed. This is also dependent on the growth rate, for the quicker the fungus grows the larger will be the area capable of

producing spores for spreading, although the number of spores per unit area of colony will be lower on a poorer than on a richer medium.

Results.

First Series—Size Cultures. (*a*) A comparison of the sizing materials can first be made on the basis of the time which elapses between inoculation with a fungus and the first signs of its sporing—that is the period at which it becomes capable of spreading infection more rapidly than by mycelial growth alone. This comparison is of the kind made by Thomson[13] (p. 156), and Davis, Dreyfus, and Holland[5] (p. 96), but their pastes were left freely exposed to the air and became infected with several fungi at once—as was shown by the occurrence of both red and green spots.[5] It is also quite possible that the fungi on one paste may have been rapidly growing ones, spores of which did not settle on the other pastes until growth had started on the first. This state of affairs might, of course, be reproduced under practical conditions, but in the long run the chance of one particular species infecting, say, cloth sized with wheat flour or farina, will be equal. The present experiments eliminate this factor of statistical probability by effecting a simultaneous inoculation (with a single species) of all the materials studied, and each fungus employed is free to develop without the possibility of inhibition by the growth of other species.

Table IX.
Time in Days between Inoculation and Sporing

	Wheat Flour			Rice Flour	Tapioca Flour	Sago	Maize Starch	Farina	Cassava	Soluble Starch
	Strong	Weak	Yeoman							
Penicillium 2	3	3	3	6	15+	8	8	7	3	6
Penicillium 4	2	2	2	3	8+	8	5	8+	2	3
Aspergillus niger	5	5	5	6	7	8	8	12	4	6
Aspergillus flavus	3	4	4	6	12	12	7	6	3	6
Rhizopus arrhizus	2	2	2	2	6	8	4	8	2	3
Cladosporium herbarum ...	2	2	2	2	4	3	3	3	2	3
Fusarium	3	2	2	3	8+	8+	8+	8+	2	5
Totals	20	20	20	28	60+	55+	43	52+	18	32

As according to this classification the smaller the index number the greater is the liability to mildew, the table gives an indication of relative "liability," as follows—

Most liable—1 Cassava and wheat flours (unsteeped).
2 Rice flour and soluble starch.
3 Maize starch.
Least liable—4 Farina, sago, and tapioca.

(*b*) From the same set of cultures a second comparison can be made by considering the degree of development both of growth and sporing on a given day. All the cultures were observed when four and eight days old, and these times are convenient to use. At four days there is a distinction between substances on which growth has or has not occurred, and after eight days between the extents of sporing. The cultures of four fungi were kept on at room temperature and again examined after 31 days. In some cases the spores formed had germinated and produced a fresh mycelial growth. This necessitates the introduction of Group 6 into the classification.

Table X.

Classification of Growth and Sporing—Size Cultures

Age		Wheat Flour Strong	Wheat Flour Weak	Wheat Flour Yeoman	Rice Flour	Tapioca Flour	Sago	Maize Starch	Farina	Cassava	Soluble Starch
4 days	*Penicillium* 2 ...	3	3	4	1	1	1	1	1	4	1
	Penicillium 4 ...	5	4	4	3	1	0	0	1	4	3
	Aspergillus niger ...	1	0	1	1	0	0	0	0	2	1
	Aspergillus flavus ...	3	2	3	0	1	0	0	1	3	1
	Rhizopus arrhizus ...	5	5	5	5	0	0	3	0	5	4
	Cladosporium herbarum	3	3	3	4	2	2	3	2	4	4
	Fusarium	4	4	4	4	1	0	1	0	4	1
		24	21	24	18	6	3	8	5	26	15
8 days	*Penicillium* 2 ...	5	5	5	3	1	2	2	2	5	3
	Penicillium 4 ...	5	5	5	5	1	2	3	1	5	3
	Aspergillus niger ...	5	5	5	4	2	3	2	1	5	3
	Aspergillus flavus ...	5	5	5	3	1	1	3	2	5	3
	Rhizopus arrhizus ...	5	5	5	5	3	2	4	2	5	4
	Cladosporium herbarum	5	5	5	5	2	2	4	3	5	4

		35	35	35	30	11	13	19	12	35	22
31 days	*Penicillium* 4 ...	6	6	6	6	3	3	4	3	5	4
	Rhizopus arrhizus ...	5	5	5	5	3	3	4	3	5	4
	Cladosporium herbarum	6	6	6	6	2	3	4	3	5	4
	Fusarium	5	5	5	5	3	3	5	3	5	4
		22	22	22	22	11	12	17	12	20	16

Substantially the same grouping as before is given at all these ages of the cultures, with cassava and the wheat flours as most suitable for growth. Growth on rice flour is somewhat slower at first, but eventually becomes rapid enough to overtake that on wheat flour. On soluble starch growth starts nearly as well as on rice flour, but slows up later, so that ultimately growth is about the same as on maize starch, on which the initial stages are slower. Farina, sago, and tapioca are again seen to be greatly inferior media for growth, for development does not proceed as far even in 31 days as on the first group of flours in four days.

First Series—Agar Cultures. In this series the growth rates of three fungi were measured, three dishes of the same flour or starch being inoculated with spores of each species. The typical examples of the daily measurements given above in Table VIII. show the evenness of growth, and so only the mean measurements of all the dishes are given here. The diameters of the colonies when five days old have been selected as representative for Table XI., whilst the complete series of mean measurements are shown graphically in Figs. 1, 2, and 3, which illustrate more clearly than the table the distinct behaviour of the three fungi. The most obvious difference is that *Penicillium* separates the sizing materials into two clear groups, *Aspergillus* into three, whilst the more quickly growing *Fusarium* merges them almost into one.

Fusarium ...	55	53	57	58	49·5	49	49	47	55·5	45·5
Totals ...	117·5	114	121	124	94·5	96	101	92	121·5	98

By considering all the fungi together, the following order is obtained—

Higher growth rate—Rice flour, cassava, and wheat flours (unsteeped).

Lower growth rate—Maize starch, soluble starch, sago, tapioca, and farina,

which agrees in general with the results obtained from the size cultures.

Second Series—Size Cultures. In this series the study was extended to other substances, certain of those examined before being repeated for comparative purposes. The maize starch and soluble starch were, however, from different samples. The procedure was exactly as before, and the results are set out below as in Tables IX., X., and XI.

In the concentrations employed, the cultures of dextrin and neutralised farina were liquid. Consequently, many of the inoculating spores sank to the bottom of the tube where growth started first. Spores were only produced when sufficient mycelium to reach the air surface had developed, thus making the dextrins appear less favourable for growth than they really are. In the farina diastase dextrin, growth was normal, and this alone is included in the table. Where normal growth occurred on the maize and acid-farina dextrins, it was, however, approximately equal to that on the farina diastase sample.

Table XII.
Time in Days between Inoculation and Sporing

	Wheat		Maize Starch	Farina			Lintner's Soluble Starch	Gum Tragacanth
	Flour	Starch		Untreated	Treated with Caustic Soda	Diastase Dextrin		
Penicillium 2	3	14	13	6	No growth	3	9	4
Penicillium 4	3	6	4	6	,,	3	16	3
Aspergillus niger ...	3	4	4	9	,,	2	6	2
Aspergillus flavus ...	3	6	6	6	,,	3	9	4
Rhizopus arrhizus ...	3	6	4	4	,,	3	3	3
Cladosporium herbarum ...	6	13+	9	13+	,,	2	9	4
Fusarium sp.	4	13	6	13	,,	4	16	16
Totals ...	25	62	46	57	—	20	68	36
Previous totals (Table IX.)	20	—	43	52+	—	—	32	—

This places farina diastase dextrin and wheat flour as giving most rapid growth, wheat starch, farina, and soluble starch the slowest, while gum tragacanth and maize starch form an intermediate class. The soluble

starch total is very different from that in the first series, but the wheat flour, maize starch, and farina agree reasonably well with the previous totals.

The degree of sporing after nine days is given in the next table, which is comparable with Table X.

Table XIII.
Classification of Growth and Sporing in Nine Days—Second Series

	Wheat		Maize Starch	Maize dextrin		Farina			Farina dextrin			Lintner's Soluble Starch	Gum Tragacanth
	Flour	Starch		Acid	Heat	Un-treated	Caustic treated	Treated and neut.	Acid 1	Acid 2	Diastase		
Penicillium 2	5	1	1	2	3	2	0	1	3	1	4	2	3
Penicillium 4	5	2	3	1	4	2	0	1	3	1	4	1	3
Aspergillus niger ...	5	3	3	3	3	2	0	1	5	1	5	3	3
Aspergillus flavus ...	5	3	3	1	3	2	0	1	4	2	4	2	3
Rhizopus arrhizus ...	5	3	4	3	1	3	0	1	1	3	5	4	5
Cladosporium herbarum	4	1	2	2	2	1	0	1	5	1	5	2	4
Fusarium	2	1	3	1	1	1	0	1	1	1	4	1	1
Totals	31	14	19	13*	17*	13	0	7*	22*	10*	31	15	22

* Medium liquid, and growth submerged.

Both these classifications give the order—

Greatest growth ... ... Wheat flour and farina dextrin (diastase).
Intermediate ... ... Gum tragacanth and maize starch.
Least growth... ... ... Soluble starch, wheat starch, and farina.
No growth ... ... Farina treated with caustic soda.

Second Series—Agar Cultures. Three fungi were again used for inoculating the Petri dish cultures, but *Fusarium* was replaced by *Cladosporium*. The mean diameters of five-day cultures are given in Table XIV.

Table XIV.
Mean Diameters of Colonies Five Days Old—mms.

	Wheat		Maize Starch	Maize dextrin		Farina			Farina dextrin			Lintner's Soluble Starch	Gum Tragacanth
	Flour	Starch		Acid	Heat	Untreated	Treated with Caustic Soda	Treated with Caustic Soda and neut.	Acid 1	Acid 2	Diastase		
Penicillium 2	25	22	20	27	24	19	0	23	24	24	24	21	24
Aspergillus flavus ...	35	33	30	35	37	30	0	43	31	32	36	30	31
Cladosporium herbarum	23	20	18	19	20	19	3	23	20	21	21	20	19
Totals	83	75	68	81	81	68	3	89	75	77	81	71	74

The totals show that on the farina treated with caustic soda *Cladosporium* alone produces very slight growth, whereas growth on the farina treated with caustic soda and neutralised is more rapid than on any of the other substances. This is largely due to *Aspergillus flavus*. Wheat flour and the dextrins come next in order, followed by gum tragacanth, wheat starch, soluble starch, maize starch, and farina. Especially in the case of *Penicillium*, growth on the dextrins is more rapid at first but slows down after some time, until, at about 12 days, the colony on the starch is equal to or

larger than that on the dextrin (Fig. 4). Thus, comparison at 10 or 12 days leaves the dextrins well behind wheat flour and about equal to the starches. This is, in all probability, due to the sugar content of the dextrin. The sugar, being immediately available as a food material for the fungus, enables this to forge ahead. As the sugar becomes exhausted, or staling products are produced, the growth rate decreases finally to become approximately the same as that on the starch.

The absence of growth, except of *Cladosporium,* on the farina treated with caustic soda is most probably due to the high degree of alkalinity of this medium, and not to any change in the starch itself. On neutralisation, this inhibiting alkalinity is removed and all the species are enabled to grow. The simpler substances formed by the breakdown of the starch now come into play, and being more easily available for growth than the starch itself, actually give a higher growth rate of the mould fungi, especially in the case of *Aspergillus flavus*, than on the untreated farina. In this case neutralisation after the treatment with caustic soda was brought about by the addition of hydrochloric acid, but probably the same effect would be produced by other acids or salts, such as magnesium chloride, which hydrolyse and give an acid solution. With zinc chloride this neutralising effect would naturally be opposed by its antiseptic action.

As in the first series, comparisons based on the two types of cultures show a general agreement, but wheat starch is placed much lower by the size than the agar cultures. Subsequent experiments, however, have shown that on size also, wheat starch gives definitely more growth than farina, and should be placed in the intermediate group.

Comparison of the Two Series—It now remains to link together the results of the two series of cultures. This can be done either by taking the actual figures obtained (using means for the substances tested in both series), or by finding some quantitative relation of the others to these in each case.

The extent of agreement between the two series of repeated substances may be gathered from the data of Table XV.

Table XV.

	Strong Wheat Flour		Maize Starch		Farina		Soluble Starch	
Series	1	2	1	2	1	2	1	2
Total Time of Sporing ...	20	25	43	46	52+	57	32	68
Growth Totals—								
Four days	24	21	8	9	5	7	15	6
Eight and nine days ...	35	31	19	19	12	13	22	15
Size of Colony at five days—								
Penicillium 2	24	25	19	20	18	19	21	21
Aspergillus flavus ...	39	35	33	30	27	30	32	30

The two samples of soluble starch differ greatly on the size cultures, but the others agree at least within the limits of grouping, and so the actual figures can be used to combine the two series of results; they are set out in Table XVI. The group numbers in the last column are obtained by combining those given by the results of the separate methods of comparison which occupy the other columns of the table.

Table XVI.
Grouping of all Substances by Degree of Liability

Sizing or Finishing Substance	No. of Days to Sporing	Growth Totals		Group Number
		Size (9 days)	Agar (5 days)	
1—Wheat flour (strong), unfermented†	22	33	62	1
2—Wheat flour (weak), unfermented† ...	20	35	61	1
3—Wheat flour (Yeoman), unfermented†	20	35	64	1

5—Rice flour	28	30	66	1
6—Tapioca flour (=Cassava starch) ...	60+	11	45	3
7—Cassava(flour)	18	35	66	1
8—Farina	55	13	47	3
9—Sago	55+	12	47	3
10—Maize starch	44	19	51	2
11 (*a*)—Soluble starch	32	22	53	2
11 (*b*)—Soluble starch (Lintner's) ...	68	15	51	3
12 (*a*)—Maize dextrin (acid)	—	13*	62	2 ?
12 (*b*)—Maize dextrin (heat)	—	17*	61	2 ?
13 (*a* and *b*)—Farina dextrin (acid) ...	—	22*	56	2 ?
13 (*c*)—Farina dextrin (Diastase) ...	20	31	60	1
14—Farina, treated with caustic soda ...	—	0	0	4
15—Farina, treated with caustic soda and neutralised	—	7*	66	3
16—Gum tragacanth	36	22	55	2

* Medium liquid and growth submerged, cf. p. T17.

† For fermented wheat flour see Table X. in "Mildew in Cotton Goods," Part III (following memoir).

Another method of comparison is by combining the growth rate results of the two series. *Penicillium* and *Aspergillus* were used in both series, and results from these can conveniently be taken together, or those given by *Fusarium* and *Cladosporium* included with little difference. The first-named pair give the following results relative to the size of the colony produced on strong wheat flour, which is taken as 100.

Table XVII.

Material	Growth Rate *Penicillium* and *Aspergillus*
Rice flour	108
Cassava (flour)	106
Farina (NaOH and neutralised)	106
Yeoman wheat flour (unfermented)	103
Strong wheat flour (unfermented)	100
Weak wheat flour (unfermented)	100
Maize dextrin (acid)	100
Maize dextrin (heat)	98
Farina dextrin (Diastase)	97
Farina dextrin (acid)	90
Wheat starch	89
Gum tragacanth	89
Soluble starch (*a*)	85
Soluble starch (Lintner's)	82
Maize starch	82
Sago	78
Farina	76
Tapioca flour (=Cassava starch)	74

This gives a grouping very like the former obtained by using the actual figures, except for the position of the treated and neutralised farina. This grouping is not strictly quantitative, as differences in the time of observation, the method of classification, and the species of fungus employed all have their effect in producing slight variations. Nevertheless certain definite points emerge and these have been confirmed a number of times in cultures on a larger scale. The amount of growth on wheat flour is about equal to that on cassava flour, but greater than that on wheat starch. Growth on the latter is greater than on either farina or sago, in which the rates are approximately equally low. The general relation also holds that growth on dextrins or flours is greater than on the corresponding starches.

DISCUSSION

The results of the present experiments confirm generally many prevalent opinions and text-book statements. Certain divergencies, however, are indicated. Maize starch does not appear to be so much more liable to mildew than the other starches, and under certain conditions it is the equal of sago, farina, and tapioca, on all of which less growth occurs than on wheat starch. The dextrins, too, are more suitable media for growth than the starches, and soluble starch appears to occupy a somewhat doubtful intermediate position in harmony with its equally uncertain chemical composition.

From the chemical point of view, one or two indications (see p. T4–8) can be obtained as to the cause of the differences exhibited by the different starches. The flours with their greater nitrogen and sugar content do support more growth than the starches, and, amongst the starches themselves, wheat and maize, with their nitrogen contents of 1·9 and 1·5% respectively (Wiesner,[14] probably the most reliable of the authorities quoted), approach the flours more closely than farina and tapioca with less than 1%. It should be remembered, however, that the samples investigated may have varied considerably from those for which the quantitative analysis is given, although qualitatively (Table V.) they agree to a large extent.

The sample of cassava (flour) contained markedly less protein than the wheat and rice flours, and yet it proved their equal for fungal nutrition—most probably because of its higher sugar content. Another illustration of the importance of sugars is afforded by the maize-acid-dextrin. In this the starch grains had not been fully converted to dextrin. Many were apparently unchanged, others which had burst still gave the unaltered starch colour with iodine, and few gave the definite brown which is given by the heat dextrin. Its sugar content was, however, high, and the greater growth on this dextrin than on the maize and soluble starches must be attributed to this factor.

In general, therefore, for all the sizing and finishing materials investigated, liability to develop mildew is closely connected with chemical properties, growth being invariably encouraged by the presence of sugars or nitrogenous material.

It should be remembered that this paper deals with materials used singly and not in commercial mixings containing softeners, weighting substances, &c., certain of which are chemically active and may exercise an important influence on the liability to develop mildew. The investigation of the growth of mould fungi on such mixings has been commenced, and it is hoped to publish the results in a later paper.

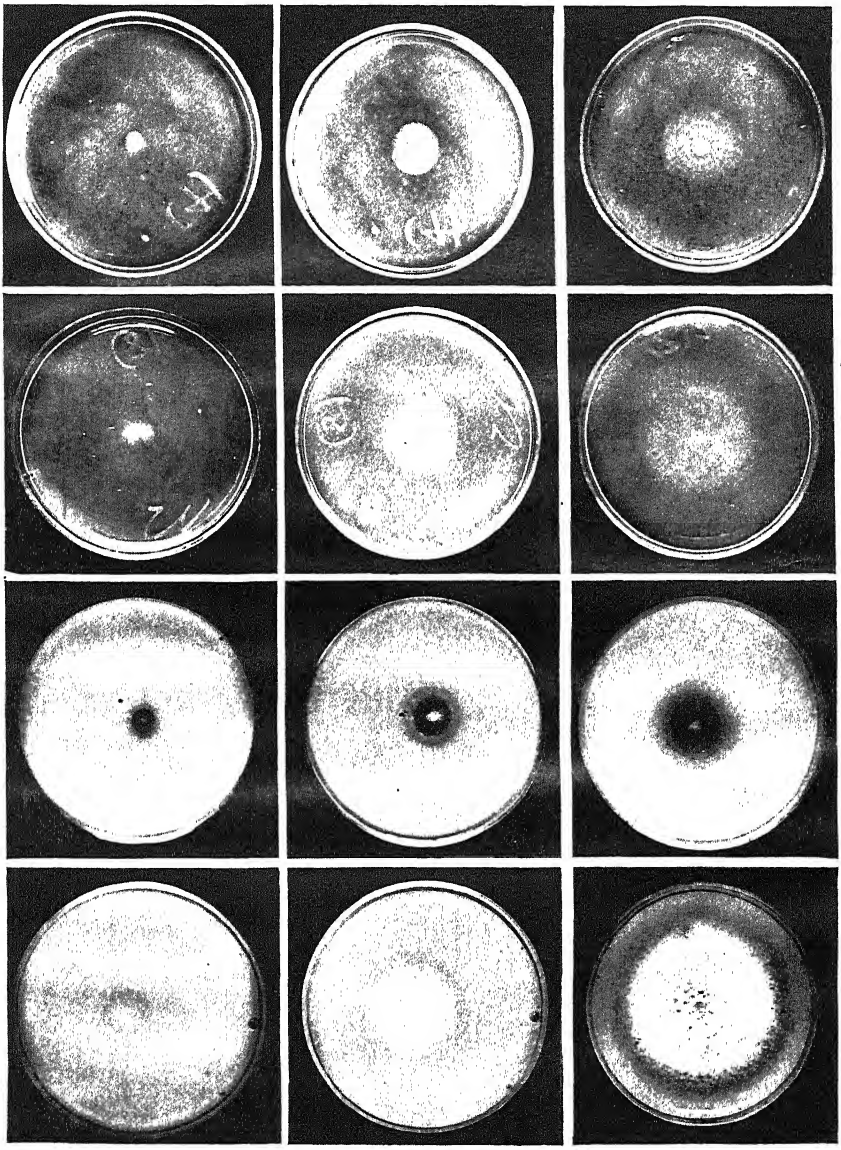

PLATE I.

2—MILDEW IN COTTON GOODS

THE GROWTH OF MOULD FUNGI ON STEEPED WHEAT FLOUR

By Leslie Ewart Morris, B.A., B.Sc.

(The British Cotton Industry Research Association).

Summary

1—The earlier literature dealing with the effect of steeping upon wheat flour is briefly reviewed.

2—A description is given of experiments involving the growth of eight species of mould fungi upon hard (=strong) and soft (=weak) wheat flours which had been steeped for different periods. All the species were isolated from cotton goods mildewed under industrial conditions.

3—The results as a whole support the general opinion that a period of fermentation decreases the liability of the flour to develop mildew, but they also emphasise a point which is not generally recognised.

Considerable specific differences exist between the various mildew-producing fungi, that is to say, under the same conditions some species behave in a markedly different way from others. For example, as the length of the steeping period is increased, the growth of *Cladosporium*, a not infrequent infection of sized warps, and *Fusarium* is increasingly checked. In other words, steeping decreases the liability to mildew so far as these fungi are concerned. On the other hand, it has little or no effect upon the growth of *Aspergillus* and *Penicillium*, which are responsible for the greater proportion of cases of mildew trouble in sized goods. If these fungi alone were considered, therefore it would appear as though steeping had no effect on liability to mildew.

4—These specific differences are also revealed when the flours are steeped with the addition of 6% zinc chloride, which decreases the liability, but much less so with some species than others. For example, the relative checking of growth of *Aspergillus flavus* is only one seventh of that of *Cladosporium*. In this case the liability does not alter with the duration of steeping.

5—The addition of caustic soda to the steep until this is neutral to litmus increases the liability, which is unaffected by the length of the steeping period.

6—If the steeped flour is washed free of acids, the liability is increased, but to a less extent than by neutralisation. Again, the length of steeping has no effect.

7—The effect produced by adding zinc chloride to the steep is also removed by washing.

8—The chemistry of the products of fermentation is discussed in relation to the growth of mould fungi.

INTRODUCTION

The relation of the growth of the mould fungi commonly occurring in cotton goods to some of the different substances employed as adhesives in sizing and finishing has been discussed in a previous communication.[7] Amongst the materials considered therein were hard and soft wheat flours, but both were investigated in the unsteeped condition, whereas it is the usual practice in the industry to subject them to a period of steeping preliminary to their use in sizing. The investigation of steeping, complicated as it is by the effect of time and the possibility of subsequent treatment, such as washing, proved so extensive, however, that it was judged advisable to deal with it in a separate paper, and to confine the previous one to an account of raw materials only.

The preliminary steeping may be carried out for different lengths of time, and to the steeped flour antiseptics may or may not be added; if not, fermentation occurs. The object of steeping is two-fold; first, the flour is

improved from the sizing point of view, and, secondly, it is considered that the liability to develop mildew damage of the goods sized with steeped wheat flour is lessened. The purpose of the present paper is to examine this second aspect of the matter alone.

Summary of Earlier Work.

The earlier writers, Thomson,[11] and Davis, Dreyfus, and Holland,[4] describe the changes which occur during the fermentation of wheat flour, but although their accounts agree in general, a certain number of ideas now obsolete are involved, and it seems desirable to accept the later and, chemically, more complete investigation of Stocks[9,10] as more likely to give a true picture of the process. Consequently the following description is based mainly on these more recent accounts.

The wheat flour, which is composed of starch, nitrogenous substances (usually included in the term gluten), sugar, cellulose, and other cell residues, and mineral salts, is mixed with water and left exposed to the atmosphere with its multitude of floating spores of fungi, yeasts, and bacteria. Some of these settle in the steeping beck and forthwith commence to grow. The first noticeable change is the development of frothing, which causes a considerable increase in the bulk of the contents of the beck, especially in hot weather. This is due to the action of a yeast on the sugars in solution, which are broken down with the production of carbon dioxide (the escape of which causes the frothing), alcohol, and a little glycerol.

After a few days, a distinct fruity odour is noticeable, owing to the formation of ethyl acetate and butyrate from the alcohol by the action of bacteria, which finally produce the free acids from their esters. Another type of bacterium is responsible for the formation of lactic acid directly from the sugars. After this the fermentation settles down and the acids accumulate, less alcohol and carbon dioxide being produced as the yeast loses its activity, partly owing to the inhibitory action of the substances which it has itself produced.

The gluten suffers but little chemical change. It becomes dispersed and forms a colloidal solution in the acids, which also, by virtue of their antiseptic properties[9,10] protect it from the attacks of putrefactive bacteria. Amongst other nitrogenous compounds present in the flour are amino-acids, and it seems probable that these are broken down with the production of various alcohols, for example, amyl alcohol, as in other cases of fermentation by yeast.[6] The small quantity of succinic acid produced (which Stocks[9] ascribes in origin to the sugar) is also probably derived from the same source.[6]

The residues of cellular tissues are broken down to more soluble or diffusible carbohydrates thus setting the starch free, but this itself is scarcely affected unless the fermentation is unduly prolonged when it is broken down to dextrin and sugars, which may then undergo changes similar to those of the sugars originally present in the flour.

Before considering Thomson's[11] remarks on the effects of the products of fermentation on the growth of mould fungi, it may be as well to prefix the warning that he does not make quite clear the two separate ways in which the acids produced may act in this direction. The first is by virtue of their properties as antiseptic substances which inhibit growth if present in sufficiently high concentration. Secondly, as acids, they increase the hydrogen ion concentration of the steep, and so render it more favourable for the growth of many species of fungi, which prefer a somewhat acid to a neutral

medium, and may not be susceptible to the antiseptic action of these compounds in the low concentrations which are yet sufficient to increase the acidity.

Thomson[11] says that the lactic and other acids produced during fermentation have a powerfully poisonous effect upon fungus or "mildew" growths, but he suggests that sufficient of these substances to prevent growth is not produced unless the steeping is carried on for two months. Further, to utilise these antiseptic properties, he emphasises the fact that the whole of the flour and liquor must be used together without washing, as the substances in question are soluble in water and would be removed by such treatment. Thomson goes on to say that as free acid has a powerful effect in aiding the growth of mildew, enough antiseptic must be produced to counteract the tendency to mildew which the free acid gives to the flour, and this tendency is lessened still more by neutralising the greater part of the free acid by the addition of soda ash or milk of lime. (But see p. T36.)

Thomson also quotes an experiment in which pastes made by boiling fermented flour (with its liquor) with water were exposed to atmospheric infection by mould fungi. On flour which had been fermented for only two weeks dense growth occurred in one week, whereas on flour fermented for two months none took place in six weeks. If, however, the flour which had been steeped for two months was washed with cold water till free from acid before making the paste, growth appeared in one week. Thomson concludes that "the small liability of fermented flour to mildew is dependent, not nearly so much on the destruction or transformation of the gluten and other nitrogenous constituents of the flour, as on the antiseptic properties of the substances into which these bodies are transformed."

In view of the indefinite and scanty character of this evidence it seemed desirable to conduct a systematic investigation of the effects of steeping on the liability of wheat flour, using the methods which have already proved useful with the simple substances used in sizing as already described.[7]

EXPERIMENTAL

Media.

Two kinds of wheat flour were employed in the present investigations. Both were commercial mixtures of hard (=strong) and soft (=weak) wheats as ordinarily supplied to manufacturers for sizing purposes.[7]

Samples of these weighing 100 grms. were steeped with water in flasks, fresh batches being started at intervals so that finally series were obtained 1, 3, 6, and 10 weeks old for the soft wheat, and 2, 8, 13, 17, and 18 for the hard wheat flour. The flasks were shaken at frequent intervals through the day to produce the mixing obtained in practice in the becks. The first few batches of 100 grms. of flour were steeped with 200 cc. of water, but, for the later ones, only 100 cc. were employed. This is nearer to the trade proportions and gives a more even mixture with less danger of the flour settling out and caking between the times of shaking. These first batches became the 10 weeks' steep for the soft wheat series, and the 17 and 18 weeks for the hard wheat series, and were included with the others as it was thought that the progress of fermentation would be but little affected. The results obtained show that this assumption was justifiable.

In the case of the soft wheat flour, samples were also steeped with 6 grms. of solid zinc chloride to the 100 grms. of flour. This is lower than the quantity recommended by Bean and Scarisbrick[1] (8%), but allows some growth to

occur in the media as used, and so permits a comparison to be made between the flours steeped for different periods which would not be possible were growth inhibited entirely.

At the end of the period of steeping, each batch was thoroughly mixed and its volume measured in a graduated cylinder so that quantities containing a definite weight of the original flour could be used as required in making up the culture media. Two types of these were employed—size paste and agar jelly—as described previously.[7]

The batches of soft wheat were diluted with water until 1 grm. of original flour was contained in 5 cc. of the mixture. For the size paste 25 cc. (=5 grms. flour) of the diluted steep were poured into 90 cc. of boiling water and boiled gently for five minutes. The resultant thin paste was tubed and sterilised in the usual way. The agar was made up by pouring 20 cc. (=4 grms. flour) of the diluted steep into a hot solution of 4 grms. of agar in 200 cc. of water and boiling. The subsequent treatment was as usual.

In the second series, with hard wheat flour, rather different quantities were used. A stiffer paste (approximately 8%) was obtained by pouring 40 cc. of diluted steep (=8 grms. of flour) into 80 cc. of boiling water, and boiling the whole as before. These proportions prevented the occurrence of a certain amount of settling out, as with the longer period soft wheat steeps, and also gave a somewhat higher concentration of the products of fermentation.

The failure of the agar to set, owing to the acidity of the batches of soft wheat flour which were fermented for long periods, was remedied in this series by increasing the quantity of agar from 2 to 3%, the same proportion of flour being still employed.

Controls were made up with unsteeped flour, which was ground with five times its weight of cold water (that is, the proportions of the diluted steep), and then poured into the agar or boiling water in the same way as the steeped batches.

Other portions of the fermented flour were filtered from their liquor in Büchner funnels at a filter pump, and then washed with cold water until the washings were no longer acid to litmus paper. The flour was then gently dried on the filter paper in an oven, removed from the paper and ground with the requisite quantity of cold water, and made up to size paste and agar jelly in the same proportions as the unwashed samples. The fresh unsteeped flour was first shaken up with water and then filtered and washed. As the soft wheat was not initially acid to litmus, the washing was carried on for a time about equal to that required to free the steeped samples from acid, to make it comparable with these by the removal of other soluble substances, such as sugars.

Considerable experimental difficulties were experienced with the hard wheat. With the 4 grms. to be used with the agar, filtering was very slow, and on drying it was not possible to separate all the flour from the filter paper without including fragments of the latter as well. As, however, paper is not available for the nutrition of the common mould fungi used, the small quantities of it which were ground up with the flour should not have affected their growth rate. The larger quantity (8 grms.) of flour to be made into the size paste could not be sucked free of its original washing water, even after a day on the pump, and as an alundum cone proved equally inadequate, the unsteeped size control had to be abandoned.

A further set of preparations was made by taking some of the diluted steep and making it neutral to litmus by the addition of a few drops of a solution of caustic soda, stirring well, and then using the same quantities as before in making up the size paste and agar media. The fresh flour was shaken up with water (1 grm. in 5 cc. as before), and then treated similarly.

The soft wheat flour which had been steeped with zinc chloride was used in the same way as the fermented flour, one batch also being filtered and washed till acid free.

The Fungi.

The seven species of fungi of the previous experiments[7] were again employed, with the addition of another species of *Aspergillus* in the hard wheat series. This was a greyish-green species isolated from mildewed grey cloth.

A complete list of the species used follows below—

1—*Penicillium* sp. 2.
2—*Penicillium* sp. 4.
3—*Aspergillus niger.*
4—*Aspergillus flavus.*
5—*Aspergillus* sp. 45.
6—*Rhizopus arrhizus.*
7—*Cladosporium herbarum.*
8—*Fusarium* sp.

As before, the tubes of size were inoculated in pairs with spores of the various fungi and incubated at 25° C. Development of growth and sporing was observed at one or two day intervals. The growth rates on agar of *Penicillium 2, Aspergillus flavus, Cladosporium,* and *Fusarium* were determined as in the previous work[7] (p. T11).

Results.

Soft Wheat Flour. Size Paste Cultures—The amount of growth and sporing observed on the size cultures was classified as before[7] into six groups—

0=No growth.
1=Growth but no sporing.
2=First sign of sporing.
3=Sporing definite but slight.
4=Sporing well advanced.
5=Sporing fully developed.

On this basis, the higher the group number the greater is the liability to mildew of the substance on which the fungus is growing.

As the tables obtained are similar to those given in the previous paper,[7] it is not necessary to set them out in full, and only the totals, obtained for all the fungi together, are shown. Following the previous plan, the time which elapses between inoculation of a paste and the first appearance of sporing of the fungus on it can be taken as a measure of the liability of the substance—the shorter the time the greater is the liability. The totals of the times taken by the seven species of fungus together are set out in Table I.

Table I.

Time of Appearance of Sporing in Days. Totals for 7 Fungi

Length of Steeping, in weeks	0	1	3	6	10
Fermented	25	41+	44	52+	56+
Fermented and neutralised	21	22	22	21	18
Fermented and washed	32	61	36	41	41
Steeped with zinc chloride	96+	96+	—	96+	—
Steeped with zinc chloride and washed	—	—	—	89+	—

The above figures may be examined from two aspects. In the first place they show the effect of increasing times of steeping on each treatment, and, secondly, they permit of a comparison of the results of these treatments at intervals in the progress of steeping.

Adopting the first viewpoint, it is seen quite clearly that a much greater period elapses before sporing appeared on the longer than on the shorter period steeps, that is, in the absence of any further treatment the liability of soft wheat flour decreases steadily as fermentation proceeds. After neutralisation, however, this progressive difference disappears and the flours fermented for all periods become approximately equal in liability. The results obtained with the washed samples were irregular but showed a slight tendency for the time of appearance of sporing to increase with length of fermentation. In the case of the cultures with zinc chloride, *Aspergillus flavus* alone of the seven species had commenced sporing before the conclusion of the experiment, and this showed no variation with length of steeping.

Viewed from the second standpoint, the results show that neutralisation annuls the effect of increased time of fermentation and brings the flours of all periods to the same level of liability—which is very slightly greater than that of the unsteeped flour, and much greater than that of the flour which has been fermented for ten weeks. Washing also increases the liability of the flour of the longer periods of fermentation, though not to the same extent as neutralisation, but decreases that of the unsteeped flour and the flour steeped for one week. The liability of the flour steeped for six weeks with zinc chloride is also increased by washing.

Another comparison may be made from the same series of size paste cultures based on the degree of growth achieved by the various species of fungi (here considered together) after the lapse of any particular period of time. Cultures ten days old have been selected in this case and the group totals for this age are given in Table II.

Table II.

Classification of Growth—10 day totals for 7 Species

Length of Steeping, in weeks ...	0	1	3	6	10
Fermented	32	30	27	25	24
Fermented and neutralised ...	35	35	34	34	34
Fermented and washed	28	19	23	22	18
Steeped with zinc chloride ...	4	4	—	3	—
Steeped with zinc chloride and washed	—	—	—	9	—

Except for the effects of washing, this table gives the same results as the preceding one, and these may conveniently be classified as follows—

Length of Steeping—

1—Untreated ... Growth is progressively retarded.
2—Neutralised ... Growth on all periods is equal.
3—Washed ... ... There is a slight tendency towards decreased growth with prolonged steeping.
4—Zinc chloride ... No change in rate of growth.

Effect of Treatment—

1—Neutralisation ... Growth increased.
2—Washing ... ... Growth decreased slightly.
3—Zinc chloride ... Growth almost prevented.
4—Washing after zinc chloride... ... Growth increased.

As essentially similar results were given at other ages of the cultures, there is no need to consider these further here. One point, however, does need consideration in more detail, and that is the different behaviour of the

various species of fungi on flour fermented for various periods. Table III. shows the group numbers of the individual species, which are collected as totals in the first line of Table II. It is seen that the decrease in the totals as steeping proceeded was due to *Cladosporium* and *Fusarium* only; if these are omitted the totals become equal.

Table III.

Classification of Growth at 10 days on Steeped Wheat Pastes

Length of Steeping, in weeks	0	1	3	6	10
Penicillium 2	5	5	5	5	5
Penicillium 4	5	5	5	5	5
Aspergillus niger	5	5	5	5	4
Aspergillus flavus	5	5	5	5	5
Rhizopus arrhizus	4	5	5	5	5
Cladosporium herbarum	4	1	1	0	0
Fusarium sp.	4	4	1	0	0
Totals—7 species	32	30	27	25	24
Totals—first 5 species only	24	25	25	25	24

This necessitates a modification of the conclusions which appeared to be warranted from the previous tables, for it is now seen that so far as *Aspergillus* and *Penicillium* are concerned fermentation has no effect whatsoever; and these are perhaps the most troublesome fungi encountered in sized goods. Considering *Cladosporium* and *Fusarium* only, it is seen that fermentation produces a material on which these fungi find it difficult or even impossible to grow.

Examples of such specific behaviour of mould fungi have been frequently encountered, and naturally this makes the question of their collective treatment extraordinarily complicated.[2]

Soft Wheat Flour. Agar Cultures—The growth rates of four species of fungi on agar jelly were determined as before.[7] The mean diameters of four colonies when five days old are given in Table IV. for *Penicillium* 2. They are also plotted in Figure 1.

Table IV.

Mean Diameter in mms. of 5 day Colonies of *Penicillium* 2

Length of Steeping (weeks)	0	1	3	6	10
Fermented	21	27	25	23	22
Fermented and neutralised	21	23	18	23	25
Fermented and washed	24	21	22	25	22
Steeped with zinc chloride	14	13	—	11	—
Steeped with zinc chloride and washed	—	—	—	20	—

The rate of growth on the fermented flour varied but little with length of steeping. There was a slight increase over the control at one week, and then a gentle fall again to the ten weeks' steep, but this was not sufficiently great to provide definite evidence. Thus the results agree with those of the size cultures for this fungus. Length of steeping also had little effect on the flour neutralised or washed after fermentation or steeped with zinc chloride. (The low figure 18 for the sample which had been steeped for three weeks and then neutralised was due no doubt to the somewhat greater alkalinity of this than the other media.) Neutralisation and washing did not appear to affect the growth rate, but a considerable degree of inhibition was produced by steeping with zinc chloride; an effect which was removed by washing.

Aspergillus flavus was also grown on agar and the results for this species are appended in Table V.

Table V.

Mean Diameters in mms. of 5 day Colonies of *Aspergillus flavus*

Length of Steeping (weeks)	0	1	3	6	10
Fermented	35	39	36	30	24
Fermented and neutralised	34	38	36	33	39
Fermented and washed	36	35	38	36	36
Steeped with zinc chloride	32	32	—	32	—
Steeped with zinc chloride and washed	—	—	—	35	—

As with *Penicillium*, there was a slight initial increase in growth with one week's steeping, but the subsequent fall with the progress of fermentation was quite definite. Again, on the neutralised and washed flours, the growth rates were nearly the same and showed no change with length of steeping. This means that both of these treatments had removed the inhibitory factors which decreased growth of *Aspergillus flavus* on the fermented flour. The effect of zinc chloride on *Aspergillus flavus* was very much less than with *Penicillum* 2, the decrease in size of colony at five days being only about 4 mm. in 36 mm., as compared with 10 in 23 in the latter species. Even so, this slight effect was removed by washing.

Table VI.

Mean Diameter in mms. of 5 day Colonies of *Cladosporium herbarum*

Length of Steeping (weeks)	0	1	3	6	10
Fermented	23	22	22	16	6
Fermented and neutralised	22	21	17	20	21
Fermented and washed	23	22	21	21	20
Steeped with zinc chloride	3	3	—	2	—
Steeped with zinc chloride and washed	—	—	—	20	—

The dimensions given in Table VI. of *Cladosporium* colonies show that less growth occurred as the period of fermentation was lengthened, the decrease being most marked after three weeks, but as with *Aspergillus flavus*, this inhibition was counteracted by neutralisation or washing. The effect of zinc chloride was much greater than with the other species, but this also showed no change with time and was removed by washing.

The fourth species grown in agar cultures behaved in the same way. The marked decrease in growth produced by fermentation was removed by neutralisation or washing, growth after the former treatment being rather greater than on the unsteeped control, or washed flour. These results are set out in Table VII. and shown graphically in Figure 2.

Table VII.

Mean Diameter in mms. of 5 day Colonies of *Fusarium* sp.

Length of Steeping (weeks)	0	1	3	6	10
Fermented	51	42	44	37	—
Fermented and neutralised	54	59	59	60	53
Fermented and washed	51	48	51	46	48
Steeped with zinc chloride	34	31	—	34	—
Steeped with zinc chloride and washed	—	—	—	48	—

In order to gain a general idea of the influence of steeping and subsequent treatment unconfused by the inter-specific differences displayed by the fungi, the colony diameters of all four species are added together in Table VIII.

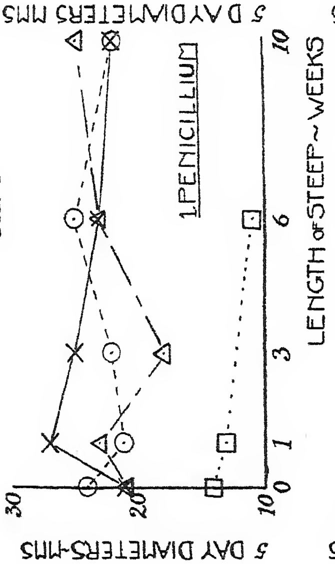

Fig. 1

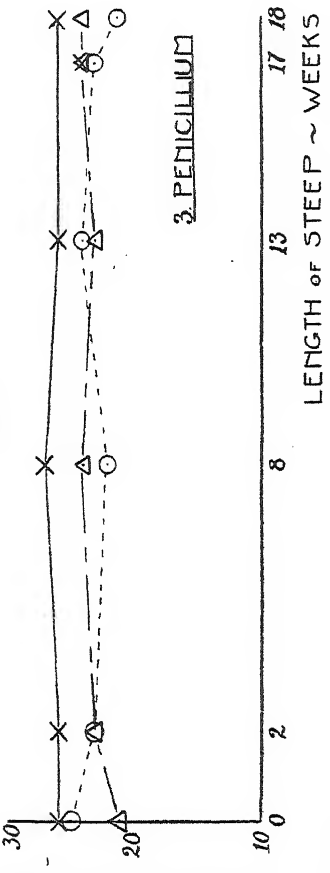

Fig. 2

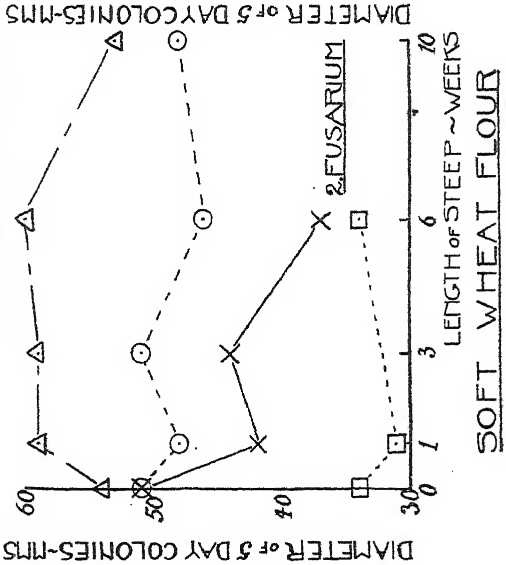

Fig. 3

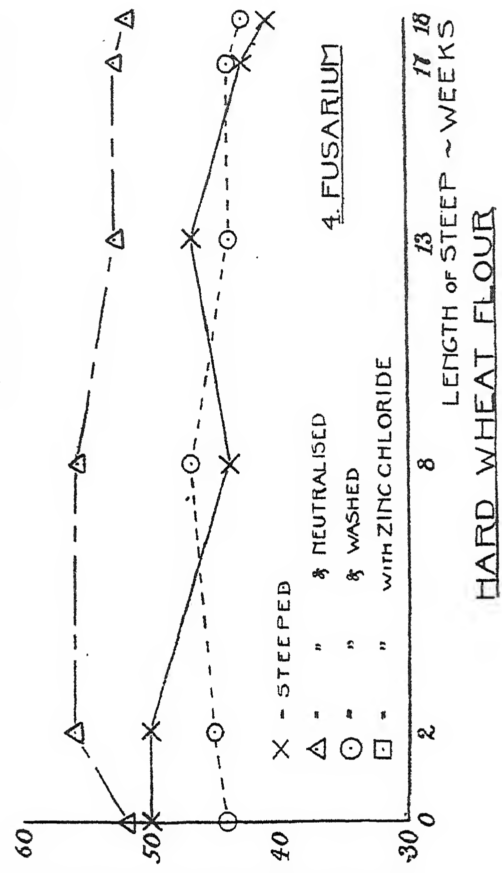

Fig. 4

Table VIII.

Totals of 5 day Diameters of Colonies of Four Species

Length of Steeping	0	1	3	6	10
Fermented	130	130	127	106	89*
Fermented and neutralised	131	141	130	136	138
Fermented and washed	134	126	132	128	126
Steeped with zinc chloride	83	79	—	79	—
Steeped with zinc chloride and washed	—	—	—	123	—

* The figure for *Fusarium* included in this total is taken as 37, *i.e.*, the same as for six weeks. It probably should be lower than this.

This table of totals, which takes all the four fungi into consideration, shows that after the first week prolongation of fermentation produced a decrease in the liability of the flour to fungal growth. This effect was removed by neutralisation with caustic soda, the growth occurring on the fermented and neutralised flour being even greater than on the control fresh flour. Washing with cold water also removed this inhibition, the resulting colonies being about equal in size to those on the unsteeped unwashed control. The growth rate of the mould fungi on the fermented flour subjected to either of these treatments showed no dependence on the length of steeping, the variations in each case probably being within the limits of accuracy obtainable by the experimental methods. Steeping with zinc chloride caused a considerable reduction of growth, but there were marked variations between the different species of fungi in this respect. Thus, with *Cladosporium*, growth on the zinc chloride preparation was only about one-eighth of that on the fresh control, whereas with *Aspergillus flavus* it was about seven-eighths. In all cases, however, the effect of time of steeping was inappreciable.

These results may be summarised as follows—

1—Fermentation ... Growth is progressively retarded with increased length of steeping.

2—Neutralisation ... Growth is increased above the control. There is no appreciable time effect.

3—Washing ... Growth is increased from the fermented to about control level. There is no appreciable time effect.

4—Steeping with zinc chloride causes considerable diminution of growth without change with time. The effect is removed by washing.

Hard Wheat Series—In this series the procedure was as before, except for the increased concentration of the size paste and the lengths of the steeping periods. The results are classified in Table IX.

On fermented flours which had not been washed or neutralised, the rate at which sporing occurred was again found to be greatest on the flour which had been steeped for two weeks, and to be approximately equal on the others. On all the neutralised pastes, sporing was earlier than on the untreated or washed samples.

The classification of growth and sporing at four days shows a marked increase from the unsteeped to the two weeks' fermented, and then a tendency to fall off as the steeping period lengthens. The seven-day totals agree in this respect, but the fall from 2 to 18 weeks is much less, the growth at 17 and 18 weeks being equal to that on the unfermented flour. The different times of steeping with neutralised and washed flour give almost equal growth at both four and seven days, that on the neutralised being greater than on

Table IX.

the untreated. The amount of growth on the washed was less than on the untreated at seven days for all periods of steep, but at first it was equal for the 8 and 13 weeks and greater for the 17 and 18 weeks' samples.

The totals of the diameters of five day old colonies of the four species grown on agar showed a tendency to decrease with increased time of fermentation on the untreated flour. On the washed they were almost equal with a possible fall at the end. The variations in the growth on the neutralised flour were rather greater than on the washed, but showed no general trend and were probably not significant. With the shorter steeping periods (0–2 weeks), growth was greatest at first on the untreated flour, but fell below that on the corresponding washed samples on which in turn growth was less than on the neutralised.

As in the soft wheat series, the effect of length of fermentation on the growth totals was not produced jointly by all the species grown. For example, *Penicillium* was unaffected, while *Fusarium* showed a marked falling off in growth with prolongation of the fermentation period. This varied behaviour can easily be deduced from the sections of Table IX. and from the examples given in Figures 3 and 4 without repeating the rather prolonged detailed analysis of the tables as was done for the soft wheat series.

Comparison of Hard and Soft Wheat Flours—For both hard and soft wheats, all the methods of comparison agree in showing a greater growth on the neutralised flour, but in each case the media were still very slightly acid (*p*H 6·0), and a further addition of caustic soda might have reduced this growth. (In this connection, see the discussion of the rôle of added alkali on p. T36.)

The untreated flour in both cases showed a tendency for growth to decrease with increasing length of steep, this being more marked with the soft than the hard wheat, in which there was an initial increase in growth with the first two weeks of fermentation.

The relation between growth on the untreated and washed media varies. With the soft wheat the classification of growth on size gives predominance to the untreated, but the time of appearance of sporing and the total growth rates reverse this relation, especially with the longer periods of steeping. This is so also with the size classification on the hard wheat flour, but the time of appearance of sporing gives the washed material a position intermediate between the neutralised and untreated.

Comparison with Starches.

Besides the consideration of the effect of fermentation on wheat flour itself, it is desirable for practical purposes to compare the liabilities of the steeped and treated products with that of untreated starches, such as maize, farina, or sago. The results of experiments on the growth of mould fungi on such substances are collected together in Table XVI. of the preceding paper, which can now be extended to include the results with fermented wheat flour. The figures obtained for the unsteeped flours in the present series agree well with those obtained before, and so a direct comparison can be made (Table X.). As before, a low number of days between inoculation and the appearance of sporing, and a high figure for growth and sporing on size and for growth on agar, indicate a high liability to develop mildew growth, and *vice versa*.

Consideration of these together gives the grouping in the last column of the table, the substances in Group 1 being more liable than those in

Group 2, and these than the members of Group 3. The grouping is only approximate, and considerable differences in degree of liability occur among the substances in one group; for example, unfermented hard wheat flour comes in the same group as hard wheat flour which has been fermented for 13 weeks, although the former is definitely more liable, as shown in Table IX., but, compared with substances such as maize starch or farina, they are both very liable to mildew growth. For comparison with starches other than those given here, Table X. may be used as a direct extension of Table XVI. of the preceding memoir.

Table X.

Grouping of Substances by Degree of Liability

Substance	Treatment	No. of days between Inoculation and Sporing (7 species)	Growth and Sporing on Size in 9 days (7 species)	Growth on Agar in 5 days (4 species)	Group Number
Soft Wheat Flour	... ...	22	33	130	1
	10 weeks fermented	56+	24	89−	3
	Ditto and neutralised	18	34	138	1
	Ditto and washed	41	18	126	2
Hard Wheat Flour	... ...	25	33	138	1
	13 weeks fermented	24	30	127	1
	Ditto and neutralised	20	33	129	1
	Ditto and washed	23	24	127	2
Maize Starch	... ...	44	19	120	2
Farina ...	... ...	55	13	113	3
Sago ...	... ...	55+	12	113	3

The general results are that ten weeks' fermentation reduces the liability of soft wheat flour to the level of that of farina and sago. Subsequent neutralisation restores the liability to the unfermented flour level, whereas washing leaves the product slightly more liable to fungus growth than maize starch. With hard wheat flour, on the other hand, the results of fermentation are not so marked, the flour after 13 weeks still being more liable than maize starch. A greater concentration of the fermented flour in making up the media probably would have given a greater effect, but even so, the soft wheat would show a larger proportionate reduction in its liability, due to fermentation.

DISCUSSION OF RESULTS

From the chemical changes which take place during the fermentation of wheat flour, it might be expected that corresponding differences would be

found in the amount of fungal growth which the flour will support. The first change results in the destruction of sugar, which, according to Stocks,[9] may be reduced from 3·62% in the fresh flour to only 0·54% after two weeks' steeping, while during the next fortnight it is completely broken down. This, alone, would tend to a slight reduction of liability to mildew during the first three or four weeks' fermentation with no change after that time, but the sugar is not merely removed from the flour—it is replaced by alcohol, esters, and eventually acids, which also affect fungal growth, if only to a small extent. Duggar[5] found that traces of ethyl alcohol caused increased germination of the spores of *Aspergillus*, but Pratt[8] obtained no effect on *Botrytis* with one part of this alcohol to six of a nutrient solution. Thomson in his first edition[11a] gives the results of an experiment in which wheat flour pastes were exposed to atmospheric infection. The addition of 1 and 2·5% alcohol to Egyptian flour had no influence at all on the time which elapsed before mould growth appeared—but he does not state what species of fungi developed.

The effect of the ethyl esters of the organic acids may vary, for Brown[4] has shown that growth of *Botrytis* may be stimulated by dilute solutions of ethyl acetate, but inhibited by the same ester in greater concentration. Pratt[8] has demonstrated that free acetic and butyric acids, even in solutions as dilute as $N/30$, prevent the germination of the same fungus. Lactic acid is less toxic, but has some effect at this concentration, whereas succinic acid has very little. As Stocks's[9] figures indicate that in six weeks' fermentation enough acid is produced to give a normal solution, a considerable diminution in growth might be expected with increasing length of steep. Complete inhibition is not likely for many other species of fungi are in all probability less susceptible to the toxic effect of these substances. It should be noted that this degree of acidity, that is the concentration of hydrogen ions, is not enough to check growth of itself, and in the case of some fungi may even favour it.

The slight reduction in total quantity of albuminoids found by Stocks[9] would not affect the liability, but the increase of the soluble part might be favourable to fungus growth. The changes in the starch and cellulose are probably too small to produce any alteration during the normal period of fermentation.

Washing with water will remove the soluble products from the steeped mixture. The elimination of the acids with their inhibitory properties will be favourable to increased growth, but, on the other hand, nutritive substances, such as the soluble albuminoids, will be removed as well, and the final relation between the untreated and washed fermented flours will be the result of the balance between these factors. That the acid effect is the more important was shown by the decrease of growth which occurred on the longer period untreated steeps, and the roughly constant amounts on the washed samples of all lengths of fermentation period.

If, instead of being washed away, the free acids are neutralised by the addition of alkali, there is no removal of nutritive substances from the flour with consequently decreased growth. The toxic effect of the acids is probably diminished in accordance with the suggestion of Pratt,[8] namely, that the inhibitory action is due to the un-ionised part of the slightly dissociated free acids, the ions of the highly dissociated salts having little or no toxicity. The effect of the addition of caustic soda then will be to increase

the growth possibilities of the steeped flour unless sufficient is added to produce definite alkalinity, when the concentration of hydroxyl ions may be great enough to prevent the occurrence of germination. The attainment of this state varies greatly with different fungi, and is also probably undesirable from the sizing point of view. When caustic soda is added in quantities merely sufficient to produce neutrality to litmus paper, the experiments show that this results in an increase of liability above that of the untreated steeped flour.

3—THE MOISTURE RELATIONS OF COTTON

THE ABSORPTION OF WATER BY COTTONS OF VARIOUS ORIGINS

By ALEXANDER ROBERT URQUHART, B.Sc., A.I.C., and the late ALEXANDER MITCHELL WILLIAMS, M.A., D.Sc.

(The British Cotton Industry Research Association.)

INTRODUCTION AND SUMMARY

The work described in the previous papers of this series[4,5,6,7] has been confined to an examination of the hygroscopic properties of one cotton—American Upland 85R. In view of the number of different cottons in use in the industry it seemed desirable to gain some knowledge of the degree of variability which might be expected to exist among these materials. Schloesing[3] found that Indian cotton was more hygroscopic than Egyptian, and Egyptian more hygroscopic than American, but this result was not confirmed by Naumburg,[2] who showed that Egyptian was very similar to the average American.

The main interest of the present work lies in the numerical data rather than in any conclusions which may be drawn therefrom. It is shown, however, that the differences which are observed among the raw cottons are considerably reduced by the partial purification effected by boiling with water, and hence it is probable that the pure celluloses of these various cottons are only slightly variable, the observed differences being largely attributable to the non-cellulosic impurities. The results differ numerically from those of Naumburg,[2] but agree with them in demonstrating that a knowledge of the hygroscopicity of a cotton is of little avail for the identification of its type.

The examination of a number of variously processed cottons has shown that the removal of non-cellulosic impurities is accompanied by a reduction in hygroscopicity, whilst the dyed material exhibits a further reduction which cannot be wholly explained in terms of the loading of the cotton with non-hygroscopic substances.

The materials used in this investigation are enumerated below—

Series A—Grey Yarns.

A 51, Sea Island.	A 54, Texas.
A 52, Sakel.	A 55, Indian.
A 53, Peruvian.	A 56, Queensland.

Series B—Water-boiled Yarns.

The same yarns as those of Series A, boiled in water for 7 hours at 25 lbs. pressure.

Series C—Texas Yarns.

(*a*) Grey. (*b*) Water-boiled. (*c*) Soda-boiled and bleached.
(*d*) Soda-boiled, mercerised, and basic dyed. (*e*) Water-boiled and basic dyed.

All the treatments mentioned above were carried out technically.

EXPERIMENTAL METHODS AND RESULTS

As comparative rather than absolutely accurate results were desired, the desiccator method[4,7] was used throughout. Two samples of each cotton were placed in weighing-bottles, and dried over phosphorus pentoxide at room temperature. They were then placed in a vacuum desiccator (one series in one desiccator) over a solution of sulphuric acid of concentration necessary to provide an atmosphere of approximately 20% relative humidity. The bottles were weighed weekly until successive weights either were constant or oscillated with small amplitude about a mean value. The acid was then standardised and changed, when the process was repeated at the new humidity. In this way the materials were exposed to atmospheres of (approximately) the following humidities, in the order—Relative humidity, per cent., 20→40→60→80→90→96→100→90→80→60→40→20. The materials were passed through an atmosphere of 100% relative humidity, in order that desorption might take place on the true desorption curve, but no reliable values for the moisture contents at this humidity can be given.

The data obtained for the raw and water-boiled cottons are recorded in Tables I. and II., and graphically reproduced in Figs. 1 and 2. They show that Schloesing's conclusions with regard to the relative hygroscopicities of American, Egyptian, and Indian cottons are not general; the hygroscopicity of a cotton provides no clue either to its origin or to its quality.

The traced curves of Figs. 1 and 2 are merely the boundary curves, and do not necessarily represent the isotherms for any particular cottons. The magnitude of the areas enclosed by these curves is, however, a measure of the variability of the hygroscopicities of these cottons. A comparison of the areas of Fig. 1 with those of Fig. 2 will show that water-boiling has occasioned an appreciable reduction in the variability. A more quantitative comparison may be made by a study of Table III. Here it is seen that the variability coefficients for the raw cottons are considerably greater than those for the water-boiled, except in desorption at low humidities. There the coefficients for the water-boiled cottons are very high, largely owing to the abnormally low values of the moisture content found for the Indian cotton. It seems probable, however, that these low humidity desorption values for the Indian cotton are affected by an unknown error, more particularly as the lowest desorption value is actually less than the corresponding absorption value. It may therefore be concluded that the considerable differences exhibited by the raw cottons are due to the presence of non-cellulosic impurities, the celluloses themselves being very similar whatever their origin.

In Fig. 3 are shown on the same diagram the results for raw and water-boiled Sea Island cotton. The curves for the other cottons are similarly disposed, so that the water content of water-boiled cotton is everywhere less than that of raw cotton at the same humidity. The differences between the two sets of results at a few humidities have been tabulated in Table IV., for which the data were obtained by interpolation on the smooth curves drawn among the experimental points. The figures show that the reduction in hygroscopicity is much greater in desorption than in absorption.

The data for the variously processed Texas yarns are presented in Table V. and the isotherms reproduced in Fig. 4. Here it is shown that the removal of the impurities from cotton reduces its hygroscopicity, in confirmation of the result previously obtained.[4] The figures for the water-boiled and dyed yarn are of interest in comparison with those for the water-boiled yarn. At low humidities the dyed yarn absorbs very little less water than the undyed, but at high humidities the reduction in hygroscopicity induced by dyeing is considerable. This reduction is too large to be ascribed to the

loading of the cotton with a non-hygroscopic substance. It must be noted, however, that this result has been obtained only for one particular type of dyeing. The evidence is insufficient to show that such behaviour is common to all dyed material.

Table V.

·226	·0396	·0400	·0373	·0473	·0399

It will be observed that the figures for the Texas cotton of Series A and B agree with those for the grey and water-boiled Texas yarn of Series C at humidities up to 85%, but that above that humidity they show an appreciable divergence. This may be due to a real difference between the materials, but it is more probable that it is merely an indication of the difficulty of obtaining correct absolute values at high humidities by the desiccator method, a difficulty which may perhaps be attributed to temperature variation, since a small change in temperature produces a change in humidity proportional to the existing humidity, and a small change in humidity at high humidities results in a large change in moisture content. The divergence noted does not, however, affect the comparative accuracy of the data for each series.

The effect of mercerisation has been and will be dealt with elsewhere,[7] so that it is not proposed to discuss the results for the mercerised yarn in any detail, but it will be noted that the mercerisation ratio for this material (1·23) is much less than the ratios previously found (1·44–1·65) for a similar cotton mercerised under different conditions. The material formerly used was mercerised loose, without tension, and brought to air-dry condition at room temperature, whilst that examined in the present work was mercerised in the form of yarn, with tension, and dried by heating. It is well known that heating causes a reduction in the absorptive capacity of cotton,[1,4] and it will be shown in a forthcoming publication that cotton mercerised in yarn form has a mercerisation ratio less than that of cotton mercerised loose, while mercerisation under tension also causes a reduction in the ratio. Since these effects are cumulative it is probable that the mercerisation ratio here found (1·23) is fairly normal for a technically mercerised cotton.

4—THE CHEMICAL ANALYSIS OF COTTON

THE ASH CONTENT AND ASH ALKALINITY OF TYPICAL COTTONS

By ROBERT GEORGE FARGHER, D.Sc., and MAURICE ERNEST PROBERT, B.Sc.
(The British Cotton Industry Research Association.)

I.—INTRODUCTION AND SUMMARY

Though the amounts of mineral matter in cottons of different origin have been determined by several observers, the figures are, almost without exception, of doubtful value, for the analyses have been made either on cotton from the bale and expressly include contaminating sand and dust, or on lint cottons without, apparently, any precautions to remove adhering impurities. The values given by Davies and Dreyfus[4] (often wrongly ascribed to Matthews), by Monie,[11] and by Mitchell and Prideaux[10], for example, include sand and dust, whilst those of Barnes[1] were determined on lint cottons, and, in the authors' experience, such figures are valid only when the analyses have been made on samples which have been carefully combed by hand, the treatment removing an appreciable amount of sand and dirt, even when the cottons appear to be quite clean. The variations observed by these workers are shown in the following table—

Type of Cotton	Ash (%)			
	Davies and Dreyfus	Monie	Mitchell and Prideaux	Barnes
Sea Island	1·25	1·10	2·2	1·2
American (U.S.) ...	1·5	1·6—2·1	2·0	1·3—1·9
South American ...	1·2—1·7	1·2—2·0	2·1	—
Egyptian	1·2—1·7	1·6—1·8	—	1·4—1·5
Indian	2·5—6·2	2·3—5·3	2·9—3·3	1·3—4·0

The mean figure quoted in Bulletin No. 33 of the United States Department of Agriculture[3] for American cottons (1·65%) is probably open to the same criticism as those of Barnes, which, however, answered the purpose for which they were intended—the proof that the high content of mineral matter in baled Indian cotton was not necessarily due to intentional falsification.

Isolated measurements which appear to exclude extraneous matter have been made by Ure,[13] who found approximately 1% of ash in a carded Sea

Island cotton, by Knecht,[6] who found 0·93% in an American yarn, and 0·89 and 1·17% in two samples of Egyptian yarn, and by Lester,[8] who found 0·82% in an American yarn, values definitely lower than those recorded above, from which the only conclusion to be drawn is that Indian cottons might be found in many cases to contain a significantly greater proportion of mineral constituents than other growths.

Davies and Dreyfus[4] suggested that an excess of ash much over 1% might be ascribed to sand and other impurities, a statement which has been repeated by Matthews and disputed by Barnes.

The procedure for determining mineral matter in cotton has already been standardised by Birtwell, Clibbens, and Ridge,[2] who showed that for many purposes it is preferable to measure instead the alkalinity of the ash, which is roughly proportional to its amount, and thus eliminate errors which are inevitable in the manipulation of small amounts of hygroscopic material. They define *ash alkalinity* as the number of milli-equivalents of acid (*i.e.* ccs. of a normal acid solution) required to neutralise the ash from 100 grms. of clean cotton. In the present work, the results are also expressed in a second form, the *alkalinity per gram of ash,* which is simply the ash alkalinity divided by the ash content. This figure is appreciably constant for different classes of cotton and therefore allows the approximate ash content to be calculated from the ash alkalinity.

Birtwell, Clibbens, and Ridge were interested in the significance of the determinations in the control of bleaching, and as they concluded that they were without value for this purpose, further work remained in abeyance. More recently, however, the determinations have proved useful in the control of the grey sour and other steeping processes. During the course of this work, the ash contents and ash alkalinities of a number of representative American and Egyptian cottons were determined, and the conclusion drawn that the *alkalinity per gram of ash* might add to the chemical methods of differentiating cottons, for the American cottons gave figures between 13 and 14, and the Egyptian cottons figures between 15 and 16, differences quite significant in view of the accuracy with which the determinations could be carried out. The experiments were therefore extended to include cottons of more widely different origins, almost all of which were well authenticated. Some of these were available only in the form of lint cotton, when it was found that reliable measurements were obtained only by carefully hand combing the material to remove adhering sand, &c., as completely as possible. Others were taken at various stages of the spinning process, and had therefore been cleaned mechanically by the machinery.

From the results it is evident that the mineral matter in North American cottons varies normally between 1·1 and 1·3%, the mean value for twelve samples examined being 1·2%. The ash alkalinity of these varied from 14·5 to 18·2. The alkalinity per gram of ash was less variable, for in ten of the twelve samples it was between 13·1 and 14·5, two samples only giving higher figures—15·3 and 15·7 respectively. The mean figure for the whole of the twelve samples was 14·1. The South American cottons examined did not differ greatly from the North American, the ash content varying from 0·8 to 1·35% for seven samples, the ash alkalinity from 10·8 to 19·5, and the alkalinity per gram of ash from 12·8 to 15·3, with a mean value of 14·3. Excluding the sample of Peruvian "moderate rough," for which all three figures were low, the ash contents varied between 1·2 and 1·35%,

the ash alkalinities between 15·2 and 19·5, and the alkalinities per gram of ash between 14·4 and 15·3, with a mean of 14·5. This last figure tended to be higher for the Brazilian than for the Peruvian cottons.

For American cottons obtained from East and South Africa, the Sudan, and Iraq, the figures were rather higher, the ash content varying from 1·2 to 1·8%, the ash alkalinity from 18 to 26, and the alkalinity per gram of ash from 14·5 to 16·0, with a mean of 15·3 for the fifteen samples. The ashes of these cottons were very white and bulky, compared with those of the other samples examined, which were compact and tinged a faint greenish-yellow.

Seven samples of American cottons grown in India gave from 1·0 to 1·5% of ash, the ash alkalinities varying from 15·3 to 22·4, and the alkalinities per gram of ash from 12·4 to 15·7, or, excluding Cambodia, which differed considerably from the others, 14·8 to 15·7, with a mean of 15·3.

For American cottons, therefore, the statement than an ash content "much" over 1% is indicative of the presence of extraneous matter is only valid when outside growths are excluded; these may be distinguished from North and South American samples, to some extent, by their ash contents and alkalinities per gram of ash.

The ash contents of six samples of Egyptian cotton were found to be very similar to those of American growths, varying between 1·1 and 1·3%, with a mean figure of 1·2. The ash alkalinities ranged from 17·3 to 19·0, and the alkalinities per gram of ash from 14·9 to 15·6, with a mean of 15·3, so that the alkalinity of the ash is generally higher for Egyptian cottons than for normal American growths. Two samples of Egyptian origin, grown in North and South America respectively, had alkalinities per gram of ash in close agreement with the mean figure for Egyptian cottons, whilst two samples of Sakel grown in the Sudan had rather higher figures.

Ash contents of about 1·2% and alkalinities per gram of ash of approximately 15·3 are therefore typical for normal Egyptian cottons, the latter figure being, apparently, more constant than for American cottons.

A series of ten native Indian cottons, some of them representative trade samples obtained in Liverpool, and others types which are being propagated by the Indian Central Cotton Committee to replace older growths, were found to contain from 1·0 to 1·6% of mineral matter—much lower figures than have been recorded by previous observers. The ash alkalinities varied between 15·5 and 22·2, and the alkalinities per gram of ash from 13·6 to 16·5, with a mean of 15·1.

It has been shown already that of the four trade samples—Broach, Surtee, Oomra, and Bengal—the Broach and Surtee had much higher phosphorus contents[5] than the Bengal and Oomra, and also higher nitrogen contents,[12] though here the differences were less marked, and, further, that the Oomra and Bengal samples showed the greatest variation from American and Egyptian cottons in the properties of the waxes.[7] Similar differences exist in the ash contents, the Broach and Surtee samples containing from 1·4 to 1·6% of mineral matter, and the Oomra and Bengal approximately 1·1%. These differences may possibly be connected with the botanical origin of the cottons, but it would be unwise to stress them at this stage in view of the uncertain origin of all trade samples.

Six samples of Sea Island cotton gave ash contents varying from 0·7 to 1·2%, the mean value being 1·0%. The ash alkalinities showed a correspondingly wide variation—from 11 to 19—but the alkalinity per gram of ash remained fairly constant, varying only from 14·4 to 15·8, the mean figure being 15·2. Three other samples—one from the Virgin Islands, one from Ceylon, and one from the Gold Coast—are included in the table, but show no point of interest save a tendency for the content of mineral matter to rise and the alkalinity per gram of ash to fall, as compared with the normal samples.

In earlier communications in this series, it has been shown that the amounts of phosphorus,[5] nitrogen,[12] and wax,[7] in the shorter-stapled material removed from card sliver during the process of combing, were greater than those in the combed material, and the same is true for the mineral matter. In the case of the wax the divergence in amount was accompanied by no significant difference in the properties, and in that of the mineral matter the alkalinity per gram of ash remains practically unchanged. This constancy in composition of the ash shows that the variation in the amount is a property of the cotton and is not due to the removal of sand or other extraneous impurities by combing, for in this case the alkalinity per gram of ash might have been expected to show significant variations. It indicates, also, that samples at any stage from the card sliver onwards are practically free from extraneous matter, and therefore give an accurate measure of the ash content of the cotton.

Summarising, therefore, it may be said that the mineral matter in North and South American, Egyptian, and Sea Island cottons usually varies between 1 and 1·3%. Higher figures are sometimes encountered with outside growths of American cotton and with native Indian types, though the differences are much smaller than were anticipated from the results of previous workers. Lower figures are found most often with Sea Island cottons. The alkalinity per gram of ash is a fairly constant factor for different classes of cotton, North and South American varieties being generally characterised by somewhat lower values than outside American, Indian, Egyptian, and Sea Island growths. The observation made previously that the ash alkalinity of a cotton is approximately proportional to its ash content is thus amply confirmed. The mean values given in the text enable the approximate ash content to be calculated from the ash alkalinity; this is especially useful in cases where the amount of material available for examination is small.

II.—EXPERIMENTAL

Ash and Ash Alkalinity Determinations.

The ashing of the cotton was carried out essentially as described by Birtwell, Clibbens, and Ridge; about 5 grms. of the sample under examination, previously dried at 110° C., was ignited gradually before an electrically heated muffle furnace, and the ashing completed at a dull red heat, corresponding to a definite current in the winding of the muffle, which produced a temperature of approximately 750° C. The silica dish containing the ash was cooled in a desiccator, immediately transferred to a weighing bottle with ground glass stopper, and weighed therefore out of contact with moisture from the air, this precaution being taken in view of the hygroscopicity of the ash observed previously. Without transference from the silica dish, the ash was then treated with an accurately measured volume (15 cc.) of an

$N/10$ solution of sulphuric acid, covered with a glass, heated for one hour on the water-bath, and then transferred quantitatively to a 100 cc. conical flask, the volume adjusted to 50 cc. by the addition of water, and the excess of acid titrated with a $N/10$ solution of sodium hydroxide, using methyl-red (1 cc. of an 0·005% solution in 80% alcohol) as indicator, the end-point being obtained by comparison with a "blank" in a similar flask containing the same amount of indicator in a volume of water equal to that of the dilute acid in the experimental flask.

Preparation of Samples.

As has been mentioned previously, a number of the samples examined were in the form of lint cotton. A representative sample of this was taken and combed carefully by hand, thus eliminating adhering leaf, seed husk, and sand. The remaining samples were in the form of card sliver, slubbing, roving, or yarns, and save in one doubtful case, where the material was obviously contaminated with leaf, were used without further treatment.

Experimental Results.

The data are given in the following tables—

5—THE SPECIFIC GRAVITY OF WOOL AND ITS RELATION TO SWELLING AND SORPTION IN WATER AND OTHER LIQUIDS*

By A. T. King, B.Sc., F.I.C.

(British Research Association for the Woollen and Worsted Industries.)

SUMMARY

This paper is for the most part purely scientific in character and does not deal directly with any definite manufacturing process or procedure, but rather with a fundamental property of wool fibre. The summary is therefore intended to indicate in a general way, without going into scientific details, the significance of specific gravity determinations in relation to other properties, such as regain and swelling, and its application as a means of investigating the effect on the wool fibre of such reagents as it may meet with in the course of manufacture.

Effect of Sorption on the Actual Determination of Specific Gravity

In the first place, in previous work necessary precautions have been ignored, particularly with regard to the sorptive power of wool, which is much more general than had been supposed. If a liquid is sorbed by wool, the observed density in that liquid will be only an "apparent density" and not the true one. Secondly, many observations recorded are valueless, as the regain of the sample used has not been specified. The wide divergence in values previously given for the density, determined in water, is accounted for by the fact that the "apparent density" in water is now shown to vary with the regain in a definite, and practically identical, manner for all clean merino and crossbred wool free from medulla.

Determinations in liquids, other than water, make it obvious that the sorptive power of wool for water has its counterpart in the case of many organic liquids, but to very different degrees, which explains the varying values obtained by previous observers using different organic liquids. This sorptive effect is a minimum with benzene, toluene, nitrobenzene, olive oil, and oleic acid, in which liquids the results for dry wool are in good agreement. The value in benzene is 1·30 (water=1), which, for reasons stated, is taken as the true specific gravity. The specific gravity at various regains, as may be required for yarn calculations, &c., is given in Table VI., Col. 5, and Graph I. No appreciable variation was found in different samples of medulla-free wool, whether merino or crossbred. Lower values are, however, obtained as the tendency towards kempy nature increases. With other liquids, especially alcohols, only an "apparent density" is obtained, which exceeds the above value by an amount depending on the extent of contraction in total volume, which has taken place as a result of sorption of the liquid by the wool. If such liquids are volatile, for example, alcohol, this corresponds to a definite regain in the vapour, in similar fashion to the regain in water vapour.

Further, the relation between the density, the swelling, and the soaking regain† can be expressed mathematically, and the swelling in water calculated from this equation is substantially the same as that obtained by direct measurement.[1] The accuracy of both methods is thus mutually confirmed.

*Published Privately April, 1923.

† By soaking regain is meant the amount taken up on immersion in the liquid, while ordinary or vapour regain is that taken up from the vapour of the liquid. It is shown in the case of water that they have the same value.

Penetration by Solvents and Oils

From this formula it appears possible, knowing both the "apparent density" and the swelling in any particular liquid, to determine quantitatively the extent of its sorption by wool. A distinction may thus be drawn, which was scarcely possible before, in the extent to which different liquids actually penetrate the fibre. This has an obvious bearing on the behaviour of different materials used in solvent scouring. Thus, for example, alcohol freely penetrates the fibre, and can therefore remove extractable matter from its interior, whereas benzene will tend to remove only surface grease. Also alcohol rapidly brings about the temporary set[2] of yarn, whereas benzene has negligible effect. Again, different wool oils may to some extent owe their varying efficiency, both in spinning and in subsequent scouring out, to the degree in which they actually penetrate the fibre rather than merely grease its surface. Thus definite information on these points should be of practical value.

Influence of Salts on Swelling and Sorption

The swelling accompanying sorption is considerably less than the volume of liquid taken up, and the volume required to be absorbed in order to produce a swelling of 1 cc. can be calculated. This has been termed the compression factor. Common salt reduces the swelling and regain caused by water alone, but also lowers this compression factor, instead of increasing it, as is the case when the regain is lowered by ordinary dehydration (with dry air or glycerine). In other words, the fibre swells more when it absorbs water from salt solution than when it absorbs the *same amount* of water from moist air. This suggests that the resilience of the fibre undergoes a different modification in salt solution from that produced by ordinary dehydration. Such facts as these may assist in interpreting the function of common salt and other substances in retarding or assisting dyeing and milling.

Density Methods of Determining Regain and of Estimating Wool-cotton Mixtures

It is shown how in the case of grease-free, undyed material, the above may be ascertained by a simple density measurement. Since grease and dye may affect the regain of cloth in irregular manner, these methods are at present put forward only as interesting developments of specific gravity determinations, but it is hoped that by suitable modification they will be applicable to commercial samples.

INTRODUCTION

The actual space taken up by a given weight of wool under various circumstances is a value which is basic to quantitative measurements of many kinds. It is required in calculations on the diameter of fibres and yarns, and on design. It is also an essential factor in the quantitative relationship of fibre diameter to count and quality, and in the accurate determination of the amounts of reagents taken up by wool. Further, a complete knowledge of the volume changes of fibre and yarn with regain, depends upon accurate values for the specific gravity of dry wool and its variation with regain. In all the foregoing, the extent of variation in specific gravity of different types of wool is of importance. Again, it will appear in the sequel that specific gravity determinations are of considerable significance in connection with the degree of penetration of solvents used for wool scouring, particularly the marked difference between alcohol and benzene, and in assisting to interpret the swelling or shrinking of wool fibre under various treatments affecting spinning, dyeing, and milling properties. Also it will appear that specific gravity measurement under suitable conditions provides a simple method of determining regain, and of estimating the proportion of cotton in wool-cotton mixtures. It is therefore remarkable that no systematic attempt has so far been made to look into the wide discrepancy of values given in the literature, and to ascertain the true value under standard conditions, and the change in value with altered conditions, of this important physical characteristic.

PREVIOUS WORK

Reference to the literature reveals specific gravity values differing much too widely to permit of the adoption of a satisfactory figure, as will be seen from the following list—

Various	—	—	1·28—1·33	Heermann, J. Soc. Dyers and Col., 1912, p. 273.

Königsborn remarks that the differing values in water previously given for different wools is probably due to the fact that they swell to different degrees in water; and also that during absorption of water by hygroscopic bodies, a compression occurs, and thus from a determination in water a higher specific gravity than the actual value will be obtained. This latter statement is correct, but with regard to the former, the present work, and the measurements on the swelling of wool fibre in water both lead to the conclusion that the average swelling is substantially the same for all qualities of medulla-free wool, though individual fibres may vary. Königsborn concludes that the specific gravity of medulla-free wool "in the open air" is 1·318 to 1·320, finer qualities being apparently slightly less dense than coarser qualities.

The initial work on this subject was for the purpose of ascertaining the volume of a given weight of wool used for sorption experiments, this information being necessary for obtaining exact values of sorption from reagents.[3] As the work progressed, however, various unsuspected factors revealed themselves, which were of obvious practical significance in several other directions, and which made it desirable to extend the investigation to find out in what degree density measurements could be made use of in the study of these problems.

GENERAL REMARKS ON THEORY

The specific gravity bottle method was used in most of the previously published work. It will be clear that by this method the weight (and hence the volume) of liquid displaced from the bottle by a known weight of the substance, only gives the true volume of the substance if there is no alteration in total volume when the substance and liquid are brought together. This is satisfied if (*a*) the substance is entirely unaffected by the liquid, or (*b*) the volume by which the substance swells (or shrinks) is exactly equal to the volume of liquid absorbed by (or expelled from) the substance when immersed. Regarding (*b*), the swelling of ordinary wool fibre in water and

various aqueous solutions, and its shrinkage in glycerine, are well known. It is also known that with most hygroscopic materials a contraction in total volume occurs during absorption of water, and this is probably true for sorption in general.

"Apparent" Density

Where this occurs, an "apparent density" greater in value than the true density will be obtained. It is therefore unlikely that condition (*b*) will be satisfied in any medium which is sorbed by wool, and this method can only be relied upon to give the true specific gravity with media for which wool has no sorptive tendency. Investigation shows that many organic liquids are unsuitable,* and that the well-known sorptive power of wool for water has its counterpart to various degrees in a number of organic media. The practical significance of this will be dealt with later. Its significance regarding the conflicting values given for the density of wool is obvious.

METHOD

The wool used had been thoroughly extracted in a soxhlet with pure alcohol. The specific gravity bottle containing the sample was dried at 102° C. under reduced pressure in an electrically-heated air bath placed in a vacuum desiccator, until constant in weight. The bottle was then attached to a tube leading below the liquid to be used, contained in a pressure flask connected with the pump. Except in the case of water, drying tubes were interposed to prevent access of moisture from the pump, and the liquids employed were thoroughly dried by suitable means before use. The apparatus was exhausted, the pump cut off, and the vacuum slowly released through the drying tubes, by which means the liquid passed over into the specific gravity bottle. This was repeated as often as was necessary to secure complete removal of air. The bottle and its contents were brought to constant temperature in a thermostat-controlled water-bath at 25° C. in every case.

APPARENT DENSITIES IN WATER

It will be evident that with water the true specific gravity will be given in the case of completely saturated wool, and for this only, since it is only in this case that the total volume of wool+water is unchanged on immersion of the wool. For all cases of incomplete saturation a contraction in volume takes place which results in a correspondingly higher "apparent" density.

Thus if W = weight of dry wool.

w = weight of moisture originally in wool.

w_1 = weight of water filling bottle.

w_2 = weight of wool plus water filling bottle.

Apparent sp. gr. of wool $\Delta_A = \dfrac{W+w}{W+w+w_1-w_2}$

For a given dry weight of wool w_2 must necessarily be the same whatever the actual regain of the wool at the time of its introduction into the bottle. Therefore, w_1-w_2 is also the same for W grams of dry wool whatever its regain may have been at the time of weighing, and $(W+w_1-w_2)$ may be written W_1. Thus the above expression may be written—

$$\frac{W+w}{W_1+w}$$

Obviously the apparent density is a maximum $\dfrac{(W)}{(W_1)}$ when $w=0$, and from this apparent density can at once be calculated for any regain by adding

* It may be remarked that mercury is unsuitable, as its surface tension prevents complete contact with the irregular boundaries of the fibre.

the weight of water corresponding to that regain, to both numerator and denominator.

Apparent Density of Dry Wool in Water

To obtain the dry weight, the sample was placed in a tube with ground-in stopper and taps at inlet and outlet. This was placed in a tube furnace, electrically-heated and controlled to give 105° C. inside the jacket and 102–3° C. inside the tube itself. A slow current of air, finally dried over phosphorus pentoxide, was drawn through the heated tube. The following results were obtained—

Table I.

Wool used	Weight of Dry Wool	Weight of Water displaced	Apparent density
Sydney 60's	1·5466	1·1077	1·3964
,,	2·0310	1·4534	1·3970
Sydney 80's	2·2616	1·6198	1·3962
Aust. 50's	3·4225	2·4545	1·3943
English Skin 56's	1·5565	1·1147	1·3963
Santa Cruz 56's	1·6907	1·2105	1·3966
English 32—36's	2·8970	2·0727	1·3976
Blackface	2·1647	1·5539	1·3962

All the above values are within the small range of 0·24%, and for purposes of calculation the value 1·3965 has been adopted. Thus, 1·3965 grams of dry wool give an increase over the weight of bottle plus water, of 0·3965 grams, or an increase of 1 gram on immersion corresponds to 3·522 grams of dry wool.

Apparent Density of Moist Wool

The following results from a series of wools (all alcohol extracted) brought to the same regain (in the humidity room), show that the agreement in dry weight apparent densities extends to moist weight apparent densities also.

Table II.

Wool used	Apparent density, Humidity about 69
Sydney 80's	1·3215
,, 60's	1·3201
Australian 50's	1·3198
English 32—36	1·3210
Blackface Kempy	1·3177

Only with Blackface is there a serious difference.

Variation of Apparent Density with Regain

It will be observed that the expression $\frac{1{\cdot}3965+w}{1+w}$ gives the apparent density when w grams of water are attached to 1·3965 grams of dry wool. This may be re-written— $\frac{100+R}{71{\cdot}6076+R}$, where R=percentage regain.

The curve shown in Graph No. I., constructed from values calculated from the expression $\frac{100+R}{71{\cdot}6076+R}$, thus gives the regain corresponding to any observed apparent density for clean wool with reasonable accuracy for all but the coarsest kempy kind.

Saturation Regain and "Soaking" Regain

The regain of saturated wool at 25° C. was found by placing a sample of known dry weight on a grid standing over water in a large stoppered jar, the whole being immersed during a week-end in the thermostat at 25° C. The stopper was removed and the wool quickly pushed into a weighing bottle also inside the jar, with a glass rod. The mean value obtained was

33%. For this temperature Hartshorne gives 31·8%, and Schloesing 34-35%. Thus, at 33% regain, the calculated apparent density is—

$$\frac{100+33}{71\cdot6076+33} = 1\cdot270$$

Now assuming that the saturated wool undergoes no further change on soaking in liquid water, this calculated apparent density is also the true density of saturated wool. As will be seen in Table VI., the values 1·267 and 1·265 were obtained for saturated wool in benzene and olive oil respectively. These are in good agreement with the above. That they are slightly lower is probably due to slight unavoidable loss of water from the wool during the evacuation of the bottle to remove the air. These closely agreeing values for *saturated* wool, in water (calculated) and benzene (observed) respectively, show that either—

(1) The amount of water absorbed from saturated air is the same as from liquid water; or

(2) If there is further absorption of water by the saturated wool (and consequently further swelling) on soaking it in liquid water, this must take place without change in *total* volume, and would not be detected by density measurements.

The calculated swelling in water (see p. T63), assuming the same regain as in saturated air, is, however, in good agreement with the observed swelling in water. The "soaking" and "saturation" regains for water thus appear to be substantially the same.*

OBSERVED DENSITIES IN VARIOUS LIQUIDS

For this series Australian 60's top, alcohol extracted, was used. The following values, including that for dry wool in water, were obtained—

Table III.

,, ...	1·7882	1·1996	0·8751	1·3043

* Work on the swelling of wool fibre in moist air subsequent to that already published[4], shows that the swelling when suspended in air above water is not quite equal to that in the liquid itself, but corresponds to 97% saturation on the curve. At present it cannot be said definitely if this very slight difference is real, or due to the air not being completely saturated with water vapour by the method employed.

The inert solvents benzene, toluene, and nitrobenzene give the lowest, and practically identical, results. The high value with water is due, as already explained, to the contraction taking place on sorption of water. The conclusion must be made that wherever a high value is shown, provided the medium is chemically inert towards wool, sorption of the medium with accompanying contraction, has occurred. It is significant that the highest values are obtained with methyl and ethyl alcohol, which have a chemical constitution similar to that of water. With amyl alcohol the apparent density, though lower than with methyl and ethyl alcohols, is still above the normal value, indicating that some sorption has taken place. Glycerine, being alcoholic in constitution, might by analogy be expected to show a slight sorption, though it is generally accepted that it completely shrinks the fibre to the same diameter as in dry air. The density values above suggest that some sorption occurs with glycerine, which would presumably require an accompanying swelling of the dry fibre, but in this case experimental difficulties, particularly of eliminating air, and of ensuring perfectly dry glycerine, may easily vitiate the result. Water will naturally be abstracted from moist solvents by dry wool, and a high value will be obtained. Thus ordinary undried olive oil gave 1·33, compared with 1·306 with dried olive oil.

Regain with Volatile Organic Liquids

The high values with methyl and ethyl alcohols made it of interest to examine whether dry wool showed a "regain" towards the vapour of these liquids in similar manner to its regain towards water vapour. Approximate regains at 25° C. were found to be as follows—

Table IV.

Liquid	Regain
Water	33%
Methyl Alcohol	26·3%
Ethyl Alcohol	21·3%
Benzene	under 0·5%

The dehydrating action of ethyl alcohol is well known, as is its power to extract water from moist wool, but that alcohol *replaces the water* so extracted appears to have escaped notice. On the contrary, the inability of alcohol to penetrate the fibre has been taken for granted from analogy with the presumed non-permeability of alcohol towards gelatine. This presumption has been used to explain the resistance of certain dyestuffs to extraction by alcohol,[5,6] but it is now evident that alcohol freely penetrates the wool substance. With methyl alcohol the regain is still higher, about 26%, as compared with 33% for water, and in each case the wool, though absorbing a large percentage of liquid, showed no sign of free liquid. As in the case of water, raising the temperature lowers the saturation regain, and on warming the tube, liquid alcohol appears in droplets on the wool, gradually disappearing again as the tube regains ordinary temperature. The rate of regain with alcohol appeared to be slower than with water, but this point was not further investigated. The reality of this regain is apparent on comparing the behaviour with benzene. With this there is no appreciable regain, though since the vapour pressure of benzene is considerably greater than that of ethyl alcohol at ordinary temperatures, there was greater opportunity of contact.

Behaviour of Aqueous Alcohol

That both water and alcohol are sorbed from a mixture by dry wool is proved conclusively by the following experiment—

Density of original mixture ... 0·9139/water at 25° C. (0·91126/4°).
Density after experiment ... 0·9135/water at 25° C. (0·91084/4°).
Apparent density of dry wool 1·390.

This value is intermediate between 1·3965 for pure water and 1·388 for pure alcohol. Thus the values for dry wool in water and alcohol given by Wilkinson and Booth (p. T55) are not reconcilable with the present writer's observations. The strength of the alcoholic solution increased slightly from 49·36% to 49·55%, showing that for approximately equal quantities of alcohol and water, the latter is sorbed in greater proportion. This is to be expected from the fact observed above that the regain for water is higher than that for alcohol.

Regain in Non-volatile or Slightly Volatile Liquids

In these cases, the saturation regains at ordinary temperature in the vapour can only be reached after very great lapse of time, making their determination practically impossible. The apparent density alone estimates only the contraction in volume, and yields no information as to the actual quantity of liquid sorbed, though it does give some idea of the relative sorption from different liquids. From a knowledge of both the apparent density and the swelling, however, the actual quantity sorbed can be calculated, as illustrated on p. T63. Information of practical importance is thus obtainable, on the one hand, regarding the relative penetration of wool fibre by different wool oils, and materials used for solvent scouring, and on the other, the part played by various salts in aqueous solution.

Regain and Power of Setting Yarn

In addition to the contrast in density and regain values for alcohol and benzene quoted above, another striking difference is shown in their effect on the properties of yarn. A warp yarn of Port Philip 80's spun to 2/32's, soaked in benzene, stretched, and allowed to dry, acquired no temporary set, but recovered almost entirely on release, just like the ordinary air-dry yarn. When soaked in alcohol, however, it behaves in a similar manner to yarn soaked in water.[2] It will stand a 25% *elongation* and, if dried before release, it still retains about 15% increase in length. If then soaked in alcohol again and dried slack, it *shrinks to* 12% *less than its original length.* It now exhibits the marked increase in elasticity shown by yarn from which the temporary set has been removed. It appears twice as bulky and altogether softer than the untreated yarn. These preliminary observations are included here as supporting the inference drawn from the specific gravity and regain experiments. A fuller investigation of this behaviour of alcohol, and the behaviour of other solvents, appears desirable.

TRUE DENSITY OF WOOL

The concordant density results obtained with benzene (and also with toluene and nitrobenzene) support the inference from the above regain and setting experiments, *i.e.* that wool has no sorptive capacity for these solvents. The consequent conclusion that the true density of dry wool is obtained in these media is further supported by the agreement between the amount of swelling in water calculated from this value and that given by direct

measurement (see p. T63), and by the absence of swelling when dry wool fibre is placed in dry benzene.*

The value at 25° C. is 1·304/water at 25° C. or 1·300/water at 4° C. for the sample of wool used.

Of the various values quoted in the literature (see p. T55) only those of Vignon, carried out on conditioned wool in benzene appear to be reliable. The effect of condition on the density is shown in Table VI.

Variation with Different Types of Wool

The impression is gained from literature statements that the density of wool varies appreciably with different qualities. For clean wool in its dry state the following values (obtained in dry benzene as previously described) indicate that it is substantially the same for all qualities which are medulla-free, and diminishes as the kempy character increases, no doubt owing to the incomplete removal of the air present in the medulla.

Table V.

Wool used	Δ/Water at 25° C.
Australian 80's	1·303
Sydney 60's	1·304
Colonial 50's	1·302
,, 46's	1·30
Lincolns 32—36's	1·294
Blackface	1·180

Variation with Regain

For these determinations benzene was used. To avoid error due to gain or loss of water from the wool to the benzene, the latter was brought to the same humidity, in the case of low humidities, by standing it in contact with a quantity of the partially dried wool before using, and for the higher humidities, by agitating with air at the corresponding humidity. Only a very slight variation in the specific gravity of the benzene was observed. The wool is very rapidly "wetted out" by the benzene, and the specific gravity bottle was filled in the ordinary way, only a brief evacuation being subsequently applied for complete removal of air, to minimise loss of moisture from the sample. The results obtained are given in the fifth column below. The corresponding apparent densities in water (last column) are included for comparison. The wool used was Sydney 60's.

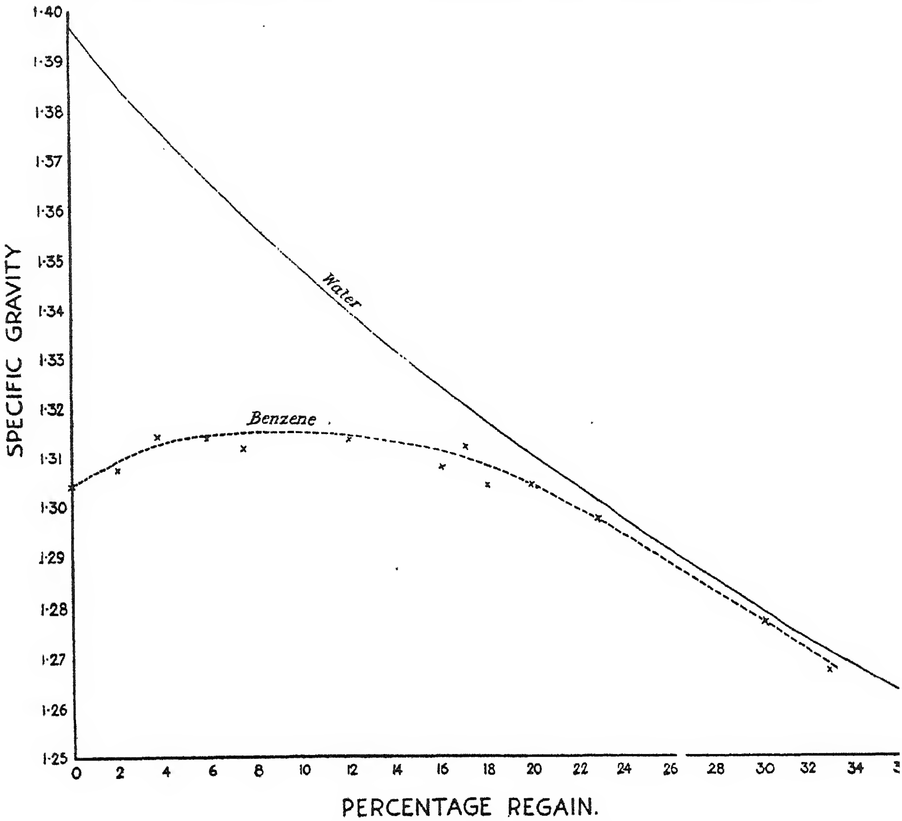
Table VI.

Regain %	Actual Wt. of Sample	Wt. of Benzene displaced	Sp. Gr. of Benzene / Water at 25° C.	S.G. of Wool / Water at 25° C.	Apparent Densities in Water at 25° C.
Zero	1·5936	1·0695	0·8752	1·304	1·3965
2·0	2·5838	1·7312	0·8752	1·307	1·386
3·75	1·6047	1·0704	0·8754	1·314	1·377
5·9	1·6383	1·0965	0·8753	1·314	1·366
7·5	1·6625	1·1093	0·8754	1·312	1·359
12·0	2·1425	1·4276	0·8748	1·313	1·339
17·0	4·4977	3·0001	0·8754	1·312	1·3205
17·3	1·3532	0·9436	0·9123 (olive oil)	1·308	1·3193
20·0	2·5256	1·6949	0·8755	1·304	1·310
22·85	2·0682	1·3954	0·8756	1·297	1·300
30·2	2·2864	1·5666	0·8756	1·277	1·278
33·0	1·7231	1·1909	0·8755	1·267	1·271
33·0	1·6868	1·2163	0·9123 (olive oil)	1·265	1·271

* These observations have been recorded in detail in a later contribution to "Swelling of Wool Fibre."[7]

(To determine the specific gravity of the benzene in each case, sufficient was transferred from the bottle containing the wool, to fill a smaller specific gravity bottle of 25 cc. capacity.)

The values are somewhat fluctuating, but the smoothed curve drawn from them in Graph No. I. indicates a tendency for the density to rise slightly in the initial stages of absorption of water to a fairly constant value over a considerable range of regain, and to fall again with increasing rapidity with ascending regain, down to a saturation value of approximately 1·27.



GRAPH NO. I.

Variation of Apparent (Water) and True (Benzene) Densities of Wool with Regain.

The average value for 18–20% regain is 1·305, which, reduced to water at 4° C., is 1·30, identical with Vignon's value for wool at normal regain, obtained by the same method.

THE RELATION BETWEEN APPARENT DENSITY, SWELLING, AND SORPTION IN PURE MEDIA

Let V_t = true specific volume of dry sorbent.

V_a = apparent specific volume of sorbent in medium used.

V_m = specific volume of medium.

S = unit volume increase on swelling.

x = sorption per gram of sorbent.

Then $V_t - V_a$ = contraction in volume per gram,

and $S \times V_t$ = volume increase per gram of sorbent.

Hence, volume absorbed $= V_t - V_a + SV_t = xV_m$.

Calculated and Observed Swelling in Water

Applying this formula to the results obtained for wool in water—

$$V_t = \frac{1}{1 \cdot 30} = 0 \cdot 7692 \text{ (Water} = 1)$$

$$V_a = \frac{1}{1 \cdot 3927} = 0 \cdot 7182 \text{ (Water} = 1)$$

If we take $x = 0 \cdot 33$ (regain $= 33\%$).

Then $S \times V_t = 0 \cdot 33 - (0 \cdot 7692 - 0 \cdot 7182), = 0 \cdot 33 - 0 \cdot 0510.$

$= 0 \cdot 2790.$

and $S = 0 \cdot 363.$

Thus the swelling in water is 36·3% by volume. This value is almost identical with the average of 36% obtained by direct measurement of individual fibres[1], and the accuracy of both methods is mutually confirmed.

Calculated Swelling in Alcohol

Similarly for ethyl alcohol we have—

Regain = 21·3%.

Apparent density = 1·388.

Density of alc. = 0·7969.

Then since $V_t - V_a + SV_t = xV_m$

$$S = \frac{xV_m - (V_t - V_a)}{V_t} = \frac{0 \cdot 2673 - 0 \cdot 048}{0 \cdot 7692} = 0 \cdot 285$$

Calculated swelling is therefore 28·5% by volume.

APPARENT COMPRESSION OF THE SORBED MEDIUM

The medium entering the wool apparently occupies a smaller volume than its normal value. This could be accounted for without assuming any real compression by a filling up of cavities within the fibre without increase in its external dimensions, but the necessary cavity volume (7% of the fibre volume calculated from the values for water) would seem large enough for such cavities to be microscopically observable. It is alternatively accounted for by assuming a real compression, caused by swelling of the contiguous structural units of the fibre against each other. This would result in a net increase in density, shared between the wool substance and the sorbed water, or other medium in some proportion which is not known, but which for comparative purposes may be assumed to be taken up entirely by the sorbed medium.

Compression Factor

The volume of medium which on being sorbed causes a swelling of 1 cc. may for convenience be termed the factor of apparent compression of the medium, or, briefly, the compression factor. The value of this factor is $\frac{xV_m}{SV_t}$. This for water=1·18 at saturation, and for ethyl alcohol 1·22.

Calculated Swelling in Moist Air

The following table shows the compression factor of the sorbed water, and the corresponding swellings, calculated from the specific gravity curve, Graph No. I., at various regains.

Table VII.

Density of Wool	Regain R	Approx. Humidity (Harts-horne)	Specific Volume × 100	Vol. of 100+R grs.	Compression Factor = Regain / Vol. incr.	% Swelling by Vol.
1·3040	0	0	76·92	—	—	—
1·3095	2	2	76·37	77·90	2·04	1·28
1·3135	5	11	76·14	79·95	1·65	3·94
1·3150	7	20·5	76·05	81·37	1·57	5·8
1·3150	10	36	76·05	83·65	1·48	8·8
1·3125	15	61	76·19	87·62	1·40	13·9
1·3040	20	81	76·92	92·30	1·30	19·7
1·2915	25	94	77·43	96·79	1·26	25·8
1·2765	30	99	78·34	101·85	1·20	32·5
1·2680	33	(101)	78·88	104·88	1·18	36·4

The calculated swellings are in fair agreement with the values from direct observation[4] at the higher regains, but somewhat greater at the lower regains. At the very low regains the possible error is large, but the increasing compression with diminished regain is unmistakable. The initial sorption of water by wool is accompanied by an apparent contraction much greater than that between alcohol and water, and comparable with that between sulphuric acid and water.* This could be explained by a mere filling up of pores, but the appreciable heat evolved rather suggests that it is of intimate character akin to chemical combination, which is no doubt connected with the difficult removal of the last traces of water from wool.

EFFECT OF SALT SOLUTION ON SOAKING REGAIN

Experiments in progress on the sorption of neutral salts indicate that sodium chloride is sorbed, if at all, in such small amount as to have negligible effect on the density of wool.

Apparent Densities of Dry Wool in Salt Solutions

These are given below, and the curve plotted from these values is shown in Graph No. II.

Table VIII.

Grams NaCl per 100 grs. solution	Spec. Gr. of Salt Solutions	Apparent Density of Wool
1	1·007	1·3842
2	1·0138	1·380
4·3	1·0294	1·3775
9·7	1·0694	1·360
9·7	1·07	1·366
14·2	1·1038	1·355
16·3	1·1191	1·3532
16·4	1·120	1·3520
21·8	1·1637	1·345
25·6	1·1956	1·3475

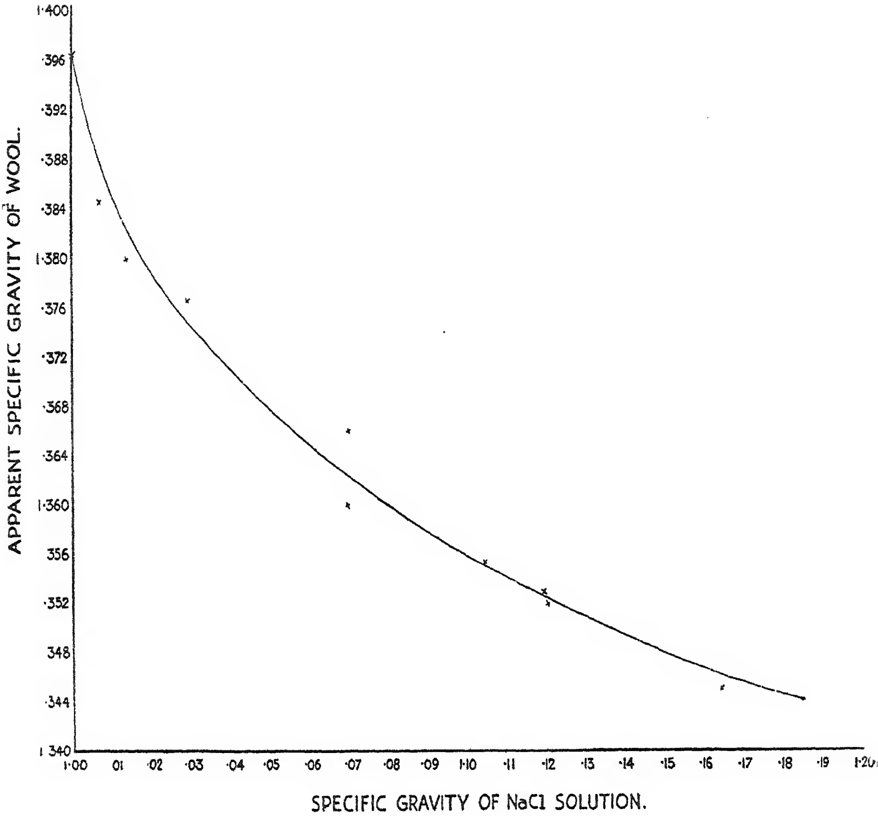
Assuming the sorption of sodium chloride to be negligibly small, the compression factor of the sorbed water, and the regain, can be calculated from the apparent density of the wool and the corresponding swelling,[8] as previously shown.

Taking, for example, a 20% solution (Δ1·12) in which the observed swelling is 31·6% compared with 38·4% in water, or 30% against the average 36·3%, and the apparent specific volume of the wool is 0·7394, we have—

$$SV_t = 0{\cdot}30 \times 0{\cdot}7692 = 0{\cdot}2308.$$

*This question is under investigation in the Physics Department of the Research Association.

Hence the regain $= 100 \times (0{\cdot}7692 - 0{\cdot}7394 + 0{\cdot}2308) = 25\%$, and the compression factor $= 1{\cdot}08$, whereas for an ordinary 25% regain the compression factor is $1{\cdot}26$.



GRAPH No. II.

Apparent Specific Gravity of Dry Wool in Common Salt Solutions.

The shrinking and dehydration produced in salt solution are thus accompanied by a *diminished* compression factor instead of the increased compression accompanying ordinary dehydration. In other words, the fibre swells more when it absorbs water from a salt solution than when it absorbs the *same amount* of water from moist air. The apparent density of wool in salt solutions may thus provide a new point of view regarding the theory of the shrinking effect of salt on swollen wool, and of its retarding effect in dyeing and milling. The extent of compression is obviously connected with the resilience of the fibre, and it is very suggestive that with caustic soda, milling power first increases and then decreases as the strength of caustic is increased. This could be explained on the hypothesis that when caustic soda solution is used to increase the swelling of the fibre as compared with water, the first additions of caustic cause further water to enter the fibre without marked decrease of compression, but as more caustic is added, a point is reached where the structure of the fibre weakens and water enters, as it does with gelatine, under a comparatively small compression, when the milling capacity again diminishes.

Mr. R. J. Smith (Chemical Assistant) has ably assisted in carrying out the experimental work.

APPENDIX

Estimations by Means of Specific Gravity Values

The following methods, while possibly of practical value, especially in cases where it may be desirable to preserve the actual samples intact, are put forward here only as interesting developments of specific gravity determinations, since the numerical factors are derived only from small scale experiments, and from undyed and perfectly clean wool and cotton. Grease and dye may affect the regain of cloth in irregular manner, also work now in progress shows that the regain of wool may in some cases be affected by finishing processes, but the possibility of adapting these methods to large scale tests of commercial samples is under consideration.

Determination of Regain of Wool

As shown on p. T57 the equation—

$$\Delta_A = \frac{100+R}{71{\cdot}6076+R}$$

gives the regain (R), corresponding to any observed apparent density in water (Δ_A). The regain of a sample can therefore be obtained with reasonable accuracy for all but the coarsest kempy kinds; either from the above equation or from the curve constructed from it, shown in Graph No. I. This method, which depends on estimating the further amount of water the sample can take up, instead of the amount which can be expelled from it, forms a useful check on the latter method, for determining the relative amount of dry wool in samples used for research purposes.

Estimation of Dry Wool Content

It may also be noted that the dry wool content of a scoured sample is approximately given by multiplying the increase in weight of a specific gravity bottle containing water and the sample, over that of the bottle with water only, by the factor 3·522, as shown on p. T57.

Example—

Weight of bottle full of water ... ... 70·2600 grs.
Weight of bottle with wool in, filled with water 70·8203
Increase ... ... 0·5603
Therefore weight of dry wool $= 0{\cdot}5603 \times 3{\cdot}522$
weight of sample of greasy taken $= 3{\cdot}65$ grs.

$$\% \text{ dry wool} = \frac{0{\cdot}5603 \times 3{\cdot}522 \times 100}{3{\cdot}65} = 54\%$$

Regain of Cotton

Further, the specific gravity method of estimating regain is applicable to any colloid showing a definite saturation regain.

For instance, pure cotton shows an apparent dry density of 1·61.* The regain of a sample can therefore be found either from the equation—

$$\Delta_A = \frac{100+R}{62{\cdot}1+R}$$ or from a curve constructed from it.

* The value found for cotton wool is 1·609, and for a sample of unsized, scoured and alcohol-extracted calico, 1·611. The possible variation with cotton of various origins has not been investigated.

Example—

A sample of cotton cloth, after keeping in the humidity room at 64·5 humidity and 75° F., gave an apparent density of 1·547.

Its regain is therefore given by—

$$1{\cdot}547 = \frac{100+R}{62{\cdot}1+R}$$

Whence $R = 7{\cdot}2\%$

The dry weight (at 102–5° C.) of a similar sample gave R=7·5%.

For cotton at 65% humidity, and 75° F., Schloesing gives R=7·3% and Hartshorne 8·6%. Hartshorne's values in this region appear too high.

Estimation of Wool-cotton Mixtures

Again, the approximate per cent. of cotton in wool-cotton mixtures is obtained from the apparent density of the dried sample.

Thus, if x = % of cotton in mixture—

$$\frac{x}{100-x} = \frac{\Delta A - 1{\cdot}396}{1{\cdot}61 - \Delta A}$$

where A is the observed apparent density.

Example—

A piece of velour cloth (alcohol extracted) gave an apparent density of 1·419, therefore the proportion of cotton = 11%.

Analysis by caustic soda gave 12·4%.

6—A COMPARISON OF MEASUREMENTS OF DIAMETERS OF WOOL FIBRES WITH THE MICRO-BALANCE AND THE PROJECTING MICROSCOPE, WITH APPLICATIONS TO THE DETERMINATION OF DENSITY AND MEDULLA (KEMP) COMPOSITION

By S. G. Barker, Ph.D., D.I.C., and A. T. King, B.Sc., F.I.C.

(British Research Association for the Woollen and Worsted Industries)

SUMMARY

The results obtained by the two methods described in this paper are in remarkably good agreement for non-medullated wools, and the gravimetric (weighing) method is shown to be a convenient means of ascertaining fibre diameter. It also affords evidence of the reliability of the regain and specific gravity values given in previous publications (Nos. 38 and 19), namely, 1·30 for the specific gravity of grease-free dry wool.

With medullated or kempy fibre the calculated diameter is less than the observed diameter, the difference increasing with the proportion of medulla present. This discrepancy is of significance in several directions. For example, the proportion of air space in the medulla itself and in medullated fibres as a whole can be approximately ascertained. It appears that the medulla itself contains about 90% air space. Also, in deriving relations between diameter of fibre and count of yarn in the case of coarse, kempy wools, allowance must be made for the fact that a kempy fibre is light in weight, as compared with its diameter. In calculating the average area of cross section, the method was adopted of calculating the area of cross section from each reading of diameters separately and then averaging the values of the cross section. This was found to give more accurate results than a calculation derived from the average diameter.

INTRODUCTION

A systematic investigation of fibre diameter, using the projection apparatus described in the Interim Report of September 1917 (p. 17), has been in hand for some time past. Although much valuable statistical information has been accumulated, it is still insufficient to meet the objects in view, as set forth in that report, and its publication is therefore reserved for the time being.

In the meantime an alternative method has been investigated, which consists essentially in weighing, by means of a micro-balance, a measured length of fibre at known humidity. The comparative results given by this gravimetric method and by direct observation of the magnified fibre are described below.

EXPERIMENTAL WORK

The Micro-balance

The form of micro-balance is similar to that in use elsewhere* and consists essentially of a filament of phosphor bronze, 0·002 cms. in diameter and 14·54 cms. long. The filament is soldered at one end to a torsion head, and at the other to a screw working in a horizontal direction by which tension can be applied without torsion. The two ends are attached to rigid brass

* *E.g.* by Dr. W. L. Balls, F.R.S., Fine Cotton Spinners' and Doublers' Association, Research Department.

pillars 1·27 cms. in diameter, mounted vertically on a rigid board. The balance beam consists of a glass rod approximately 0·006 cms. thick, at one end of which a fine sharp-angled hook is bent by fusion. The other end is drawn out to a fine point. The whole beam is constructed by drawing out solid glass rod to the required thickness. The beam is carefully balanced at the middle of the wire at right angles to it, so as to swing horizontally when in the zero position. It is then fixed in position by a drop of molten shellac and left to harden. The beam for these experiments was approximately 20 cms. in length and the indicator end swung over an arc of radius 10 cms. The circular scale was prepared photographically from an accurately divided celluloid protractor. This was mounted on a vertical brass disc immediately behind the beam, and so arranged that it was capable of adjustment in three directions at right angles. The filament was brought centrally through a hole at the middle of the scale and the beam swung in front of it parallel to the plane of the disc. The whole apparatus was enclosed in an air-tight glass case and carefully calibrated. The wire was initially free from torsion. The deflections of the indicator across the scale were read through a telescope placed two metres away from the instrument (and focussed so as to give an enlarged image of the indicator and scale). It was thus possible to read the deflection to 0·05 degree.

Calibration—The calibration was effected by means of a series of known weights of various values within the limits of the instrument's capacity, carefully noting the deflections. The zero reading was checked after each ten weighings and the calibration repeated after each fifty readings. In both cases any change was unnoticeable. A calibration curve was plotted and the actual weights in grams read off from it. These readings were also supplemented by checking the values so obtained by calculation.

Possible Variation of Balance with Humidity and Temperature Changes—The balance was used in a room maintained at constant temperature throughout. Frequent readings were taken of the temperature to detect any possible variation, but this was found to be unnecessary. A correction had to be made for the change in weight of the fibres due to the humidity of the atmosphere in the room. Observations of wet and dry bulb temperatures were taken close to the apparatus throughout the course of the experiment.

Preparation of Fibres before Weighing

Measurements with the projecting microscope are made on fibres mounted in Canada balsam, and as previously shown (Publication No. 11, p. 34) in this medium the diameter obtained is that of the clean dry fibre. Thus to compare the two methods the fibres to be weighed must be free from adhering greasy matter, and the dry weight of the fibre employed for the diameter calculations. The fibres to be weighed were therefore extracted with alcohol and well rinsed in distilled water. A special fibre cutter was made by means of which the fibres could be cut exactly to a known length. This consisted of two knife edges (safety razor blades) which could be brought down between two sets of rubber pads between which the fibre was held under just sufficient tension to straighten it, but not to extend it by any stress. The distance between the knife edges could be accurately determined. The method was thoroughly tested by dealing with some hundreds of fibres of different diameters and thickness. Finally, a complete test by both weighing and microscopic methods was applied to Botany wool fibres from

a top of 70's quality. They were left in the atmosphere for some time before weighing in order to obtain equilibrium with the humidity of the room, and then weighed individually on the micro-balance, after cutting to the desired length. They were immediately mounted on a microscope slide in Canada balsam in the same order as for weighing, and their diameters measured at ten points along their length by the projecting microscope method, magnification 1,000 diameters (*J. Text. Inst.*, 1924, **15**, T334, and Assoc. Report, No. 11, p. 17).

Method of Calculation

Assuming a cylindrical structure* the weight of a dry fibre of—

$$\text{Length} = l,\quad \text{Density} = \Delta,\quad \text{Diameter} = d,$$

is given by—

$$W = \frac{\pi \Delta d^2 l}{4} \qquad \text{A}$$

W is known from the micro-balance, $\Delta = 1{\cdot}30$, and l was taken as 7·80 cms. throughout. The latter is a purely arbitrary value suited to the length of the fibres under test. In the present work the fibres are not measured dry, but conditioned.

From formula A we get—

$$d^2 = \frac{4W}{\pi \Delta l}$$

If R is the regain and W_R the weight of the conditioned fibre, then the dry weight of the fibre is—

$$\frac{100 W_R}{100+R}$$

Therefore for dry fibres $d^2 = \dfrac{400\ W_R}{\pi \Delta l\,(100+R)}$

$$\text{or } d = \sqrt{\frac{400\ W_R}{\pi \Delta l\,(100+R)}} \qquad \text{B}$$

The values taken for the regain at the various humidities were those as obtained by Shorter and Hall (Publication No. 39), and for the density of wool (dry) that given by King (Publication No. 19), namely, 1·30. In the case of the appended tables, the individual weights of the fibres were taken, added together, and the average taken. Since d^2 is proportional

* Actually the cross section of wool fibre is slightly elliptical, and if d_1 and d_2 are the major and minor axes respectively—

$$W = \frac{\pi \Delta d_1 d_2 l}{4}$$

but unless d_1 and d_2 are very different, $d_1 \times d_2$ is sensibly the same as d^2. In measuring mounted fibres with the projecting microscope, the chance of measuring at the major or minor axis respectively is very small, and the average value obtained will naturally approximate to the mean of the two.

to W, this is equivalent to obtaining the root mean square of the diameter as shown below.

$$W = \frac{\pi d^2 l \Delta}{4} \text{ for dry fibres.}$$

For constant length $\frac{\pi l \Delta}{4}$ is constant, say $= K$.

Then from above $W = Kd^2$.

Now if n fibres are taken of weights—

$$W_1, W_2, W_3, W_4 \; . \; . \; . \; . \; . \; . \text{ to } W_n$$

and corresponding diameters—

$$d_1, d_2, d_3, d_4 \; . \; . \; . \; . \; . \; . \; . \; . \; . \text{ to } d_n,$$

we have, if W_m = mean weight of fibre.

$$W_m = \frac{W_1+W_2+W_3+W_4 \; . \; . \; . \; . \; W_n}{n}$$

Now mean square diameter $= d_m{}^2$ is equal to—

$$d_m{}^2 = \frac{d_1{}^2+d_2{}^2+d_3{}^2+d_4{}^2 \; . \; . \; . \; . \; d_n{}^2}{n}$$

$$\text{also } W_m = \frac{Kd_1{}^2+Kd_2{}^2+Kd_3{}^2+Kd_4{}^2 \; . \; . \; . \; . \; . \; . \; Kd_n{}^2}{n}$$

$$i.e. \; W_m = \frac{K\,(d_1{}^2+d_2{}^2+d_3{}^2+d_4{}^2 \; . \; . \; . \; . \; . \; d_n{}^2)}{n}$$

or substituting from above—

$$W_m = Kd_m{}^2,$$

or $\qquad W_m$ is proportional to $d_m{}^2$.

In deducing relationships between fibre diameter and quality, other observers have taken the *arithmetic* mean diameter as their basis. The square root of the mean of the squared diameters is, however, the correct value to employ. As an example, the appended table gives the arithmetic mean diameter as $2{\cdot}134 \times 10^{-3}$ cm., and the root mean square diameter as $2{\cdot}166 \times 10^{-3}$ cm. This, of course, is only identical with the arithmetic mean, when the fibres are all of the same diameter (*i.e.* when the standard deviation is *nil*), and becomes greater than the arithmetic mean, the less uniform the fibres are in thickness. This point can be discussed more conveniently in connection with the general results on fibre measurement, which it is hoped will shortly be published.

The actual measurements of the 70's top taken by the projecting microscope were recorded, the squares of the diameters calculated, added together, the mean taken, and the square root of the mean value extracted. It was found that the average value of the diameter, as estimated by the micro-balance, is $2{\cdot}164 \times 10^{-3}$ cms., and by the micrometric method as $2{\cdot}166 \times 10^{-3}$ cms. The two methods are therefore in good agreement in this case. There is also confirmation of the value 1·30 for the density of dry wool assumed in this paper. The coefficient of variation in the case of the micro-balance was 13·75% and the standard deviation 0·1904, whilst with the projecting microscope the coefficient of variation was 17·25% and the standard deviation 0·3681.

The balance averages a whole fibre, while the microscope gives measurements at a number of points. Under the conditions shown in the following

table it is seen that the micro-balance is a reliable instrument for the diameter determination of fibres—

Mean Weight in Scale Divisions = 1·952

Hence Diameter, using micro-balance (Formula B, page T70), $= 2{\cdot}164 \times 10^{-3}$ cms.

Mean Square of Diams. = 4·691

Hence Diameter, using microscope, calculated from mean square $= 2{\cdot}166 \times 10^{-3}$ cms.

Arithmetic Mean Diameter from Table I $= 2{\cdot}134 \times 10^{-3}$ cms.

Diameter of Medullated or Kempy Fibres

In this case the results obtained by the two methods cannot be compared so simply since the diameters obtained from the micro-balance assume a fibre to be solid and of uniform density, whereas the medulla portion is more or less of honeycomb structure. Thus, the diameter calculated from the specific gravity 1·30 is considerably less than the observed diameter obtained by the project microscope, the difference increasing with the proportion of medulla. The two methods, however, allow an approximate determination to be made of the relative proportions of medulla, air space, and solid wool substance contained in the fibre. Assuming that the actual substance of the medulla (excluding the air or gas) is of the same density as wool, the proportion of air or gas in the medulla and in the fibre as a whole is given in Table II, the last two columns. The mathematical details and formulæ appear in the Appendix.

The following procedure was adopted. A large number of Scottish Blackface fibres, which had been specially selected on account of their large medulla content, were weighed on the micro-balance. The weights

were carefully recorded and each fibre given a number. They were next mounted on microscope slides in the same order as that in which they were weighed. The external diameter and the diameter of the medulla core were measured on the photo-micrometer at ten places on each fibre, both measurements being made at the same time along the same diameter of the fibre. The results obtained from measurements of 150 fibres are not conclusive and further work is necessary. Nevertheless they are interesting and important. By calculation from the formulæ it is found that in medulla fibres of the type taken—

(1) The percentage volume of air space enclosed in the medulla is approximately between 50–60% of the total fibre volume.

(2) In the medulla itself the percentage of air space is about 90% by volume, so that the actual medulla substance only occupies about 10% of the medulla core.

(3) For fibres containing large quantities of medulla, allowance must be made, in deriving relations between diameter of fibre and count of yarn, for the fact that a kempy fibre is light in weight as compared with its diameter. Further work is projected to determine the density of the medulla substance, without which the other formula cannot be calculated accurately. The large percentage of air space in medulla probably accounts for anomalous effects in the dyeing of medulla-containing fibres.

(4) In cases where fibres are practically all medulla, with just a thin outer wall, the readings showed that the cross section was less circular with increase of medulla and the method could not be utilised in these cases. Tests therefore had to be confined to those cases where approximately circular medulla existed.

Table II., following, gives the results of experiment on ten typical fibres. It is seen therefrom that the mean percentage of air space to volume of medulla is 90·89%, and that of air space to total volume of fibre is 54·55%. Taking 40 fibres, the mean value of the former was 88·5% and for 120 fibres the value of the latter was 54·99%.

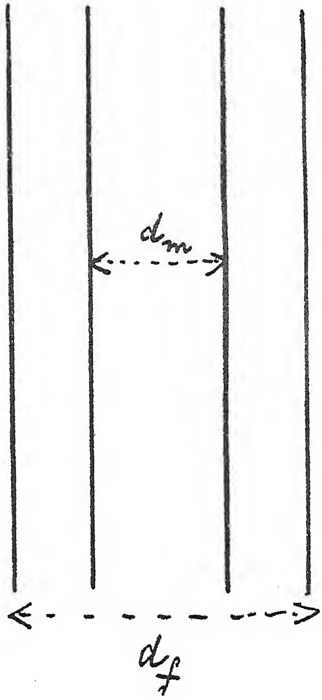
APPENDIX

Estimation of Medulla (calculations)



Suppose the fibre to be of cylindrical cross section. Let the outer, or fibre diameter, $= d_f$, and the inner, or medulla diameter, $= d_m$. These can both be measured. Then if Δ is the density of wool substance, and also assumed to be the same for medulla substance, namely, $\Delta = 1{\cdot}30$, and if l the length is constant (7·80 cms. in our experiments), we have—

Weight of whole fibre, if solid,=

$$\frac{\pi \Delta l (d_f)^2}{4} = W_f.$$

Now let the actual weight of the fibre from micro-balance $= W_b$.

From this figure a value d_b can be calculated which would be the diameter of a solid fibre of the same weight as the one taken, *i.e.* without medulla.

Thus $$W_b = \frac{\pi \Delta l (d_b)^2}{4}$$

and $$(d_b)^2 = \frac{4 W_b}{\pi \Delta l}$$

Now volume of whole fibre $= \dfrac{\pi l (d_f)^2}{4} = V_f.$

And since volume $= \dfrac{\text{Weight}}{\text{Density}}$ therefore

volume of the solid portion as calculated from micro-balance $(=V_b)$.

$$V_b = \frac{\pi l (d_b)^2}{4}$$

Therefore volume of air enclosed—

$$V_a = V_f - V_b = \frac{\pi l (d_f^2 - d_b^2)}{4} \quad . \; . \; . \; . \; . \; . \quad C.$$

Now the volume of medulla core—

$$V_m = \frac{\pi l (d_m)^2}{4}$$

Therefore percentage ratio of air enclosed in medulla core by volume—

$$\frac{V_a}{V_m} \times 100 = 100 \times \frac{\frac{\pi l}{4}(d_f^2 - d_b^2)}{\frac{\pi l}{4} d_m^2} = \frac{(d_f)^2 - (d_b)^2}{d_m^2} \times 100 \quad . \; . \; . \; . \quad C.$$

Percentage ratio of air enclosed to total volume of fibre by volume—

$$\frac{V_a}{V_f} \times 100 = \frac{d_f^2 \times d_b^2}{d_f^2} \times 100 \quad . \; . \; . \; . \; . \; . \; . \quad D$$

7—A TEST TO DISTINGUISH BETWEEN VISCOSE AND CUPRAMMONIUM ARTIFICIAL SILKS

By O. S. Rhodes, M.Sc.

This test depends for its application upon the fact that Viscose Silk invariably contains sulphur whereas cuprammonium silk is free from this element.

Reagent

A solution is made up containing 1% silver nitrate, 4% sodium thiosulphate, and 4% caustic soda. The silver nitrate, dissolved separately, is added to the sodium thiosulphate, also dissolved separately, and the precipitate which first forms redissolves. The caustic soda is now added and the whole brought to the boil and filtered.

Test

The two silks are separately immersed for 1 min. in the solution at boiling temperature. The cuprammonium silk remains white whereas viscose silk is coloured a deep red-brown, the difference between the two being very distinct. Dr. Kurt Götze (*Melliand's Textilberichte*, Oct. 1925, abstracted in the *Silk Journal*, 20th Nov. 1925), discusses a means of distinguishing between cuprammonium and viscose silks, and advocates heating with a 1% ammoniacal silver nitrate solution when cuprammonium silk remains white and viscose silk turns brown. The thiosulphate-silver solution gives, however, a very considerably deeper shade to the silk than the ammoniacal-silver solution.

The two tests were compared by boiling cuprammonium, viscose, vistra, and nitrate silks separately in the respective solutions for 1 min. Vistra silk is a variety of viscose thought to contain more sulphur. In order to express the depth of colour produced by these tests without reference to actual tested samples, the colourations obtained are expressed as though they were % dyeings of Chlorazol Brown M, the shade of which is very close to that produced by these tests. The colouration due to ammoniacal silver solution is perhaps a little yellower.

	Götze Test	Present Test
Cuprammonium Silk ...	0% Chlorazol Brown M	0% Chlorazol Brown M
Viscose	·3% ,, ,,	2·5% ,, ,,
Vistra	1% ,, ,,	4% ,, ,,
Nitrate	·6% ,, ,,	3·25% ,, ,,

It will be noticed that nitrate silk also gives a brown colouration with these solutions. The test may therefore be used to distinguish between cuprammonium and nitrate silks though its value as a means of distinction between cuprammonium and viscose silks is unaltered. Nitrate silk may also be identified by the characteristic blue colour reaction with diphenylamine sulphate.

Dr. Götze, in the article quoted above, also mentions the colouration given by nitrate silk and suggests that the colouration does not depend upon the sulphur content of the silk but is probably due to the precipitation on the fibre of a brown colloidal form of silver. He has probably overlooked the fact that in the manufacture of nitrate silk, denitration is effected by passing the silk through a bath containing alkaline sulphides, and it appears to the author that this is probably the source of a certain amount of sulphur left in the silk, which results in the colouration.

The thiosulphate silver solution is also employed as a test for oxycellulose, its use for this purpose being first described by W. Harrison, *J. Soc. Dyers and Colourists*, 1912, **28**, 361. Consequently, certain forms of cuprammonium silk, which are known to contain oxycellulose may respond to this test though the colouration would be of a greyer or less brown character. This fact also negatives the suggestion that the colouration is due to precipitation of brown colloidal silver, since in the oxycellulose test the deposit is grey.

The shades obtained by the use of ammoniacal silver solution, though increased slightly by longer boiling, do not approach those obtained by the present method. This is probably due to the fact that the caustic soda, being a strong base, dissolves the sulphur more rapidly than ammonia.

The present method is recommended as giving a much more satisfactory distinction between cuprammonium and viscose artificial silks.

The author is indebted to Messrs. Tootal Broadhurst Lee Co. Ltd. for their permission to publish these results.

8—THE REFLECTION OF LIGHT FROM TEXTILE MATERIALS AND THE PHYSICAL CAUSES OF THEIR LUSTRE

By George Alfred Rea Foster, B.A., A.Inst.P.

(The British Cotton Industry Research Association).

I.—INTRODUCTION

The work summarised in this paper was suggested by the experimental researches of Adderley[2,3] and Oxley,[2] Barratt,[4] and Denham and Lonsdale,[5] upon the lustre of cotton and other textile materials.

Several suggestions have been put forward as to the causes of lustre in textiles, especially with regard to the high lustre of mercerised cotton. A summary of these was given by Adderley.[1]

Barratt,[4] as a result of a series of measurements of the reflection of light from cotton and mercerised cotton, states—"There seems to be little doubt that the lustre can be accounted for by a single surface reflection," and the object of this investigation was to test this view by applying the laws of reflection to the discussion of the reflection of light by the surfaces of textile fibres.

The work was in the first place undertaken in order to find an explanation of the correlation observed by Adderley[3] between the shape of the cross-sections of cotton hairs and the intensity of the light reflected by them, and so to disclose the cause of their lustre. It was found that the observed variation of the amount of reflected light could be explained by considering only external reflections from the surface of the hairs, and as a result of this the work was then extended to a general discussion of the conditions necessary for high lustre in textile materials.

Comparison of the further theoretical results with experiment showed that in some cases the reflection and scattering of the light from the inside of the hairs cannot be ignored, but that, as far as the lustre is concerned, sufficiently accurate and valuable conclusions may be drawn by dealing with external reflections alone.

An exact calculation of the reflection of light from textile materials requires mathematical methods and will be published elsewhere. This note will be confined to a simple discussion, in the next section, of the agreement between the calculated reflection from cotton hairs with Adderley's measurements, and then, in the final section, on the conditions for high lustre in textile materials, with special reference to cotton, a summary is given of those results of the work which are of practical importance.

II.—THE REFLECTION OF LIGHT FROM COTTON HAIRS AND THE GEOMETRICAL SHAPE OF THE HAIRS

In the work[3] on the lustre of raw cottons, the intensity or amount of the light reflected from pads prepared by laying the hairs as straight and parallel as possible in a thick layer on a plane surface was measured. This was found to be closely correlated with the ratio of the axes of the cross-sections of the hairs, the intensity of the light increasing as these axes became more nearly equal.

In order to find a theoretical explanation of this correlation it was necessary to take some ideal geometrical form, to which the actual shapes of cotton hairs approximate. The form chosen was the surface traced out by the boundary of an ellipse, when its centre moves uniformly along a straight line at right angles to the plane of the ellipse while its axes rotate.

The intensity of the light reflected from a pad of such ideal hairs can be calculated, and when only reflection from the external surfaces of the fibres is considered, it is found under the conditions of the above experiments to be proportional to the following expression—

$$\frac{1}{a.c}\left[\frac{(a/b)^2+1}{(a/b)^2-1}\right]$$

in which c is the number of convolutions per unit length, and a and b are the greatest and least axes of the cross-sections.

In comparing this with the experimental results, the mean value of a for each cotton was obtained from Adderley's original measurements of the cross-sections of the hairs, the measurements of 200 sections of each cotton being used. The average of the quantity in brackets was calculated from the same observations and the number of convolutions was counted on centimetre or two centimetre lengths of 50 to 80 hairs taken at random from each cotton.

The results are given in Table I. and the theory is compared with experiment by dividing the values of the above expression by the corresponding observed intensities of the reflected light to give the figures in the last column. If the theory is correct, these ratios should be constant, but in judging them the experimental error must be taken into account. Their probable errors cannot be calculated accurately, but they are certainly not less than 6%. Most of the cottons give a reflection which is, within the limits of error, in accord with the theory, and considering the departures

of some of the cross-sections from the elliptical shape, the few large deviations are not surprising. The consideration of external reflections alone

is therefore practically sufficient to give an adequate account of the variation of the intensity of the reflected light with the geometrical shape of cotton hairs.

According to the theory the variation of the intensity of the reflected light with the shape of the sections is due to the presence of the convolutions; if the hairs are not convoluted the reflection would not vary in the same manner. At first sight the above formula may appear to disagree with the observed absence of correlation between the reflection and both the number of convolutions and the diameter of the hairs. This absence of correlation is, however, only apparent, and is due to the small variation in these two quantities being masked by the far greater variation in the shapes of the cross-sections.

III.—THE CONDITIONS WHICH FAVOUR HIGH LUSTRE IN TEXTILE MATERIALS

The last section dealt with the reflection of light from prepared pads of parallel cotton hairs. Since it is upon the reflecting properties of such pads that the lustre of the finished textile product partly depends, the conclusions (many of which have already been proved by experiment) derived from the theoretical investigation of these properties will first of all be discussed.

If a pad of fibres is held between the eye and a source of light in such a position that the light is reflected from the surface of the pad into the eye and with the fibres perpendicular to the direction of vision, the intensity of the reflected light is practically the same whatever angles the incident light and the direction of vision make with the surface of the pad and the surface has not a lustrous appearance.

When, however, the fibres are parallel to the plane containing the incident light and the direction of vision, or the plane of incidence, the reflected light is greatest when these two directions make equal angles with the surface of the pad. In this position the light is said to be specularly reflected and the lustrous appearance of the surface of the pad is due to the reflection in this direction being greater than that at other angles. In this paper the word lustre will be used to describe the property of a surface of reflecting more light in one particular direction and must therefore be clearly distinguished from the intensity or amount of reflected light. The lustre depends upon the way in which the intensity of the reflected light changes when the angles of incidence and reflection are varied, and the greater the specular reflection as compared with that at other angles the greater the lustre of the surface. A pad of fibres, then, always has a low lustre when viewed in a direction perpendicular to the direction of the fibres, and may have a high lustre when it is looked at along the direction of the fibres. It is this lustre of the pad when the fibres are parallel to the plane of incidence which determines the lustre of the finished product.

It is therefore necessary to consider the influence of the arrangement and properties of the fibres upon the lustre in this position. In the first place, since all the fibres cannot be in the plane of incidence unless they are straight and parallel to one another, the maximum lustre of which they are capable is only obtained when the fibres are as straight and parallel as it is possible to make them. The lustre is also obviously limited by the lustre of the surfaces of the fibres themselves, which is determined by the

smoothness or degree of polish of these surfaces. After this it depends almost entirely upon the geometrical shape of the fibres.

The fibres of greatest lustre are those which, like silk and artificial silk, are free from convolutions and folds in their surfaces and are therefore cylindrical. Their cross-sections, however, are not necessarily circular. With perfectly smooth cylindrical fibres, all the light reflected in the plane of incidence is specularly reflected and the lustre is a maximum. When the fibres are not cylindrical the lustre is less and decreases as the fibres depart more and more from the cylindrical form, that is, as the curvature of their surfaces in directions parallel to their axes increases.

High lustre in convoluted cotton hairs is therefore produced by those conditions which make the hairs approach most closely to a cylindrical form. These are—

(1) Low maximum diameter or ribbon width.
(2) Low number of convolutions per unit length.
(3) Low ratio of the axes of the cross-sections.
(4) Uniformity in these three quantities.

It will be noticed that these conditions are also those which determine high specular reflection, the variation of which with the shape of the hairs was discussed in the last section. The third factor has by far the most influence upon the lustre, partly because the variation in the shape of the cross-section between the different varieties of cotton is considerably greater than that of the number of convolutions or of the ribbon width, and partly because as the ratio of the axes approaches unity the lustre increases extremely rapidly. But the other factors should not be ignored. It must also be noticed that, when either there are no convolutions or the axes are equal, the hairs are cylindrical and the remaining factors have no influence upon the lustre. In these limiting cases the formula given on p. T78 no longer holds.

Any process, therefore, which decreases the ribbon width, removes convolutions and improves the shape of the cross-section, will increase the lustre of cotton. These are precisely the effects of mercerisation under tension and the high lustre of mercerised cotton is thus accounted for. The ratio of the axes for mercerised cotton is about 1·6 to 1·5, and slight improvements in the shape of the section would produce increasing improvements in the lustre. Thus, other things being equal, a change in a/b from 1·5 to 1·2 would approximately double the intensity of the specularly reflected light.

The lustre of a surface made up of a series of parallel single yarns laid side by side on a plane is the same as that of a fabric composed entirely of floating threads, and is therefore of importance in dealing with the lustre of fabrics. It might at first sight appear that the lustre of such a surface would be greatest when the plane of incidence is parallel to the direction of the fibres on the upper surface of the yarn. The problem, however, is different from that of parallel fibres already discussed, since the fibres on the surface of the yarn are curved. Calculation shows that the lustre is greatest when the pad of yarns is viewed in a direction parallel to the axes of the yarns. This lustre decreases as the twist in the yarns is increased and is, for the same angle of twist, independent of the diameters of the hairs and of the yarns, except so far as the diameter of the hairs affects the lustre of the raw material. Further, the lustre of the yarns cannot exceed the lustre of a pad of parallel hairs.

Except when the angles of incidence and reflection to the surface of the pad are nearly equal, the amount of light reflected from these floating threads is a maximum when they are perpendicular to the plane of incidence and a minimum when they are in the plane of incidence. This fact is, of course, made use of in weaving those fabrics in which patterns are produced by floating threads. It will be noticed that when the angles of incidence and reflection are equal, the pattern is almost invisible. The important fact from the present point of view is, however, that the contrast between the warp and weft faces is increased by increasing the lustre of the yarns.

Finally, in order to prevent misunderstanding, it must be remarked that very high lustre in the finished fabric is not always desirable. Much depends upon what may be called the character of the lustre. Thus, Barratt[4] points out that on account of the interlacing of the yarns in some fabrics, the surface appears as a series of bright points on a darker ground, and "it is to this distribution of the points of high light that some lustrous cotton fabrics owe their beauty." This breaking up of the light must involve a reduction in the magnitude of the lustre, but the contrast between the bright points and the remainder of the surface increases with increase in the lustre of the yarns themselves and therefore in the lustre of the raw material.

IV.—SUMMARY

(1) The results of a theoretical investigation of the lustre of cotton and mercerised cotton are discussed.

(2) In the first place the theory shows that the observed variation of the intensity of the light reflected from raw cottons with the geometrical shape of the hairs may be accounted for by single surface reflections.

(3) The lustre of textile fibres depends upon the lustre of the surfaces of the fibres themselves and upon the shape of the fibres. The fibres of maximum lustre are those which are cylindrical and the lustre decreases as the fibres depart from the cylindrical form.

The factors which determine the lustre of raw cotton are discussed.

(4) The lustre of the finished product cannot exceed the lustre of the raw material in the form of a pad of parallel hairs, and the maximum lustre is only obtained when the hairs are laid straight and parallel. The lustre of single yarns thus decreases with increase in the twist.

(5) The variation of the lustre of yarns with the position of the plane of incidence is considered and the results are applied to a brief discussion of the lustre of fabrics.

9—THE TIME FACTOR IN HAIR TESTING

By JAMES CAMERON MANN, M.A., B.Sc., and
FREDERICK THOMAS PEIRCE, B.Sc., F.Inst.P.

(The British Cotton Industry Research Association).

INTRODUCTION AND SUMMARY

The breaking load of a cotton hair does not depend entirely on the strength of the hair, but varies a great deal with the rate at which the tension is increased or rather with the time allowed for the hair to stretch to the breaking point. The more time the hair is given to yield, the lower is its resistance at any given extension or at rupture, owing to the fact that its elasticity is imperfect. To enable comparison to be made between tests carried out at different rates and to determine the best rate for testing, this time effect must be known quantitatively. There are other factors also which may lead to different results of breaking load tests on similar samples, namely, errors in the instruments and changes in atmospheric humidity.

Tests at rates of loading between 0·003 and 1 gram per second were carried out on a modified type of O'Neill hair-strength tester, designed to avoid several errors to which the usual type is subject. Instead of water, the liquid used to control the tension was a solution giving a definite relative humidity (66% in these experiments). The samples were conditioned over the same solution before testing. The dimensions of the apparatus were standardised to give a suitable calibration constant and rate of loading, and to minimise a correction necessitated by the extension of the hair. To avoid the error involved in guessing when the hair just comes under tension, the upper grip was on a lever by which an extremely small but definite tension was obtained at the beginning of an observation.

For higher speeds, a Torsion Balance hair tester was used, with a moving arm made extremely light to avoid jerky tensions. It was operated by hand to the beat of a metronome, at rates of loading from 1·4 to 3·6 grams per second. Similar specimens were tested on the two instruments at speeds so close that no appreciable time effect was to be expected, and a comparison of the frequency curves gives little indication of error in the more rapid machine.

As random variations among individual hairs might obscure the time effect, special precautions were taken in sampling, which was also controlled by measurements of hair weight and rigidity. These showed that the hairs broken at the different speeds were on the average very similar. The variety studied most thoroughly was a fine Sakel cotton, and the effect was also measured on a mercerised Sea Island, a rough Peruvian, and New Guinea Durango (Upland class).

At the lower rates of loading, the breaking load increases considerably, that of Sakel changing from 4·09 to 5·58 gm. within the range of the O'Neill tester. Beyond a rate of 1 gram per second there is no sure indication of

any change. Between the usual rates on the two testers (say 0·1 and 2·0 grams per second) the difference is about 20%. As this varies with the cotton, it is desirable that the difference should be diminished by testing on the O'Neill instrument at 0·5 gram per second, on the Torsion Balance at 1·5 to 2 grams per second. Quick testing has the advantage not only of saving time, but also of giving a result closer to the upper limit, which has more absolute significance than values which depend as much on the speed as on the specimen.

An approximation to the lower limit of breaking load was made by hanging weights of 2·13 grams on a number of Sakel hairs, half of which broke in 30 days. As a general principle, when the method of testing varies, the samples being similar, comparison is sounder on the basis of the order of individual results, median to median, &c., rather than on the magnitude of deviations, mean to mean. The change in breaking load was thus followed for weak and strong hairs separately for breaks occupying from one-third of a second to a month. A simple and general expression is obtained by plotting the breaking load against the time occupied in loading to rupture—when the time is divided by 10, the breaking load increases by a constant amount (roughly one-tenth of the breaking load for a time of 10 seconds).

The change of breaking load is explained as an effect due to elastic imperfection, and the empirical law can be directly related to a similar law for the decrease with time of the load on a thread kept at a constant extension. Extreme limits can be set to the increase and decrease of breaking load with time, showing that the above logarithmic law can only be regarded as a convenient approximation over the range of experiment.

Stronger hairs of a variety appear to be affected more than weaker hairs, and this would be expected if the internal thickening of the hair wall is less perfectly elastic than the surface layers.

EXPERIMENTAL METHODS

Modified O'Neill Instrument

For measuring the breaking load of single cotton hairs at moderate speeds the simple but delicate instrument designed by O'Neill[4] was used, with a few modifications designed to avoid errors which affect the result of measurements on the usual form.

Dimensions—Since a cotton hair extends about 7% of its length before breaking, the float sinks by this amount and this exaggerates the breaking load.

Let—

Breaking load $=F$ gms.	Inner diameter of tube $=a$ cm.
Length of specimen $=l$ cm.	Outer diameter of float $=b$ cm.
Extension at break $=el$ cm.	Height of liquid at zero $=h_0$ cm.
Density of liquid $=\rho$ gm./cc.	,, ,, ,, break $=h$ cm.

Then the volume of liquid run off and measured,

$$V=\frac{\pi}{4}(a^2-b^2)\left(h_0-h+el.\frac{b^2}{a^2-b^2}\right)$$

The load $F=\frac{\pi}{4}\rho b^2(h_0-h-el)$

$$=\frac{\rho b^2}{a^2-b^2}.V.\left[1-\frac{el}{F}\cdot\frac{\pi a^2b^2\rho}{4(a^2-b^2)}\right] \qquad (1)$$

$=$factor $\times$ reading $\times$ (1 $-$ correction).

The correction can be calculated if e/F be taken as 0·01 at about 60% R.H., a value obtained from figures given by Barratt.[1]

The error due to hair extension is generally neglected but may be several per cent. unless the dimensions are chosen to reduce it.

The following dimensions are given as their adoption would make results more accurately comparable—

Inner diameter of tube (*a*) 4·5 to 5·0 cm.; length about 30 cm.
Outer diameter of float (*b*) 1·0 to 1·2 cm.; length about 15 cm.
Free length of mounted hair (*l*) 1·0 cm.

Longer specimens increase the probability of flaws and vitiate comparison of long with short hairs by approaching the tips of the latter.

Solution—When the hairs are broken over a free surface of water, their moisture content may correspond with anything from saturation to the humidity of the laboratory. Any errors that might arise from varying moisture content were avoided by conditioning overnight the test sample of hairs over a 40% solution of calcium chloride (density 1·272 at 15° C.), and using the same solution instead of water in the O'Neill apparatus.

Upper Grip—Perhaps the greatest source of error in the ordinary form of this apparatus is due to the difficulty of estimating the beginning of tension on the specimen. Ordinary hairs are so fragile that a "slight" tension as judged by eye may be a very appreciable fraction of the breaking load, and it was found impossible to test tendered hairs without the new type of upper grip shown in Fig. I. Essentially this consists of a small lever, whose

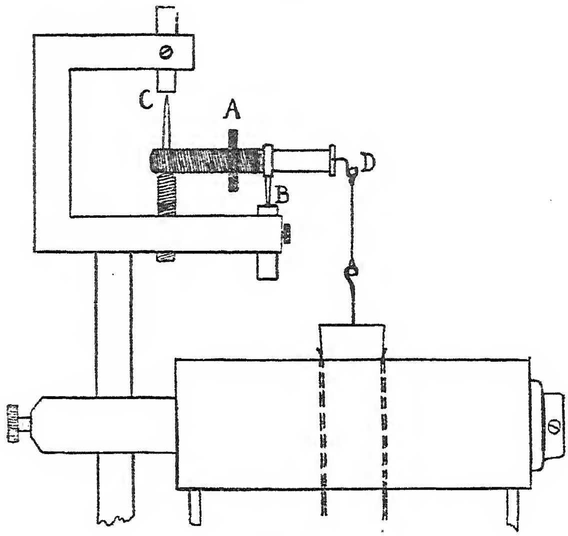

FIG. 1

moment can be adjusted by the nut A, mounted on two small needles B, which rest in point and line depressions on the stand, a third needle coming to rest against a plane C when a very slight tension is placed on the specimen. Owing to the downward movement of the grip and the delicacy of the lever it can easily be held in balance so that the release of two drops of the solution is sufficient to pull it over, with a tension of about 0·005 gram.

The grip D can be made to take paper mounts or torsion pendulums (small transverse rods). The latter were used in this research, as a preliminary measurement of rigidity[5] gives a measure of the fineness of each hair and a control on the sampling, with no great addition of labour.

The rate of loading is measured by the volume emitted in a fixed time (from Equation 1) and was varied by modifying the jet of the outlet tube,

capillary tube being used for the slowest rate. As it took about half an hour to break a hair at this rate, the top of the apparatus was completely enclosed to maintain the conditions of humidity.

Torsion Balance Instrument

With rates of loading above 1·0 gram per second, the interval between rupture and closing the jet may become appreciable in comparison with the total time of break, introducing a systematic error. For greater speeds, therefore, a Torsion Balance Hair Tester was employed, a modification of that used by Farrow and Neale.[3] The results from this instrument may be subject to an uncontrollable error due to oscillations of the beam, but these can be minimised by reducing the moment of inertia of the beam. In the present instrument the latter is a light duralumin pointer with a loading arm fixed at an angle 25° above the line of the pointer. The inertia is very small and the scale open and even over the usual range of testing. A constant rate of loading was maintained with the aid of a metronome.

Sampling

The variety tested most thoroughly was a high-grade Egyptian, Govt. No. 30 Ex. Super Sakel, and the following method of sampling was adopted. From the fairly large sample available, small tufts of hairs were taken at random from all parts and thoroughly mixed by repeated drawing and doubling. This in turn was reduced in bulk by a similar process and cut to a length of 15 mm. From this sample, single hairs were taken at random and counted out into bundles of twenty, fifty in all, which were weighed on a sensitive micro-balance (1 cm. deflection=0·0118 mgm.). The bundles were grouped into five lots of 200 hairs, so that the mean hair weight of each lot was approximately the same.

The hairs were mounted on torsion pendulums by molten shellac,* conditioned overnight over a 40% solution of calcium chloride (which gives 66·3% R.H. at 20° C.), and their rigidity determined before breaking on the O'Neill apparatus. Each lot was broken at a different rate of loading, but the rigidity was measured under the same conditions in each case. It had previously been found that a fairly high correlation (around 0·6) exists between the square root of the rigidity of single hairs and their breaking load, so that the approximate constancy of the mean rigidity shows that the lots would have given very nearly the same breaking load if broken under the same conditions.

The samples for the Torsion Balance were taken from the same final sample in the same way and mounted on paper grips, the weighing and rigidity measurements being omitted as the sampling was shown by the former lots to be sufficiently constant.

In the case of the Sea Island cotton, the sample consisted of the hairs of median length from a lightly combed seed. These were mercerised, cut to a length of 15 mm., and counted out one by one into bundles of 30 hairs, two of which were tested at each rate, with the rigidity control test.

Peruvian Full Rough was chosen as a good example of thick-walled hairs. New Guinea Durango is a type of Mexican cotton usually classed

*In one set of 200 tests, the mean breaking load of those hairs which broke within 1 mm. of the ends was separately evaluated and found to be slightly, though not significantly, greater than that of the remainder. Shellac melts below 80° C. and there seems no real danger of weakening the hairs by this method of mounting.

as an Upland. The samples were made as for the Sakel but the weight and rigidity control dispensed with, except on the lot tested at 0·098 gram per second.

EXPERIMENTAL RESULTS

The following tables show the mean values obtained on each of the samples examined—

Table I. (A)

Govt. No. 30 Ex. Super Sakel. 200 specimens at each rate.

* On Torsion Balance tester.

The breaking load of the Sakel cotton hair is plotted against rate of loading in Fig. 2, Curve 1. At slow rates the change is very considerable, the apparent strength increasing by 34·5% on increasing the rate from 0·0029 gm./sec. to 0·665 gm./sec. Over the same region the mercerised hairs show an increase in breaking load of 39·5%. Beyond this point these curves do not show any significant change. Only with the New Guinea Durango does the apparent strength continue to increase up to the highest rate.

There remains just a possibility that the apparent strength may be slightly diminished by vibratory stresses in the Torsion Balance tester. In Fig. 3 the frequency polygons of breaking load of the Sakel at the rates 0·986 and 1·43 gm./sec. are compared, and they appear to approximate to very much the same smooth curve. If any error is introduced by momentum in the latter, it is too small to raise any objection to the use of the Torsion Balance tester for ordinary testing purposes. though sufficient to obscure

FIG. 3

a slowly increasing trend at high speeds. The slightly lower value at 3·57 gm./sec. is almost certainly due to vibratory stresses introduced by the excessive speed in a proportion of the tests.

A Standard Rate of Testing

Though all the varieties show this effect of speed, they do not all vary to the same extent; the relative strength of the Sakel and Durango hairs changes greatly and even reverses with rate of loading, similarly with the other two. From the shape of the curves it seems desirable to test as fast as is consistent with accuracy. It is suggested that a rate of loading of 0·5 gm./sec. should be adopted for the O'Neill test and 2·0 gm./sec. for the Torsion Balance test. The result of the latter would then be about 9% greater than that of the former, and this some 10% greater than the result of the usual O'Neill test at about 0·1 gm./sec.

It appears that a greater degree of significance for the result and a more accurate comparison between results of different observers, as well as economy of time, are secured by testing at the higher speeds, and the use of the Torsion Balance tester is strongly supported. Nor should it be forgotten that the strains which break cotton hairs in practice are generally applied rapidly.

The Time of Break

From the point of view of testing routine, this effect must be considered as a relation between rate of loading, the testing condition, and mean breaking load, the result, and this is now satisfactorily defined. As a property of the hair, the effect is, however, not suitably described by these quantities. It is really a time effect of elastic imperfection and the most convenient way to express the time variable, a question which will be more fully discussed in a paper on the corresponding effect in yarns, is by the logarithm of the time between the beginning of loading and rupture.

When different materials are tested in identical ways, the mean values give the most significant comparison. When similar samples are tested in different ways, this is no longer so. Strong and weak hairs may be affected differently, *e.g.* the lower values may be crowded together, the higher ones opened out, and the means will then refer to very different specimens. Provided the conditions do not actually reverse the apparent strength and the samples have the same distribution of properties, the values are more significantly compared by considering their order, thus comparing the weakest under the several tests, the strongest, and the values which lie at the middle and the quarters in order of strength, called respectively the median, and the first and third quartiles. This is the nearest that can be done to actually testing the same hair under different conditions.

By this method of expression, it becomes possible to pursue this relation to much slower breaks, namely, by hanging small weights on a number of hairs and noting the time of survival. It is then a very probable assumption that the hairs will break in the same order as if tested slowly under steadily increasing load. The hairs were mounted on paper grips and suspended by thin strips of rubber (to absorb vibrations) from a wooden beam resting on rubber pads in the humidified box, which will be described in another paper. They were thus kept at constant temperature (20° C.) and humidity (66% R.H.), protected from vibrations and draughts. A weight of 2·13 gms. was then carefully suspended from each hair and the time at mounting noted.

The following table gives the times within which the hairs broke, the number of new breaks being noted at each examination—

Table II.

Time (hours)	0	½	1	17	18	120	128	171	208	238	256
No. broken	3	3	1	5	2	1	3	1	2	1	2
Time (hours)	333	480	544	574	621	710	728	883	945	960	1128
No. broken	1	1	1	1	1	1	1	2	1	2	1

At 1680 hours, 25 unbroken.

The effect of speed on the apparent strength of weak, medium, and strong hairs can now be followed by plotting the breaking load and time of break (or its logarithm) for the corresponding elements of all the frequency curves. Under steadily increasing load, the time is given by dividing the breaking load by the rate of loading. Under a constant load the conditions are rather different and a fairer comparison is obtained if the period of survival be doubled to give the time of break, for then the maximum final load and the average load over the time are the same as if the tension had been slowly increased from zero. As the time varies a million-fold over the whole range, it is immaterial if the best factor for comparison differs somewhat from 2.

Table III.

† This point deviates from the best straight line by much more than three times the probable deviation of the other points, a sampling irregularity only. It is therefore ignored in calculating the best straight line.

*Similar results on yarns show that log T under constant load is almost normally distributed. This figure is given by assuming the two quartiles equally distant from the median. It is not used in calculating the line, but the latter passes almost exactly through it.

The results given in Table III. are plotted in Fig. 4. There is no definite or consistent evidence of curvature in the relation between F and log T, and this is well expressed by a straight line through the points, the deviations from this being random and not excessive as sampling differences. The same applies to the results on the other cottons when plotted against log T.

It would be expected, if the weak and strong hairs were similar save for area of cross-section, that the lines for the different quartiles would converge to a point on the zero of breaking load, *i.e.* the change in strength

be proportional to the strength. There is, however, no apparent time effect on the weakest hairs and the sets of points appear rather to converge at a positive value of the strength. To obtain the best general expression, the straight lines were drawn by the method of least squares* and are given

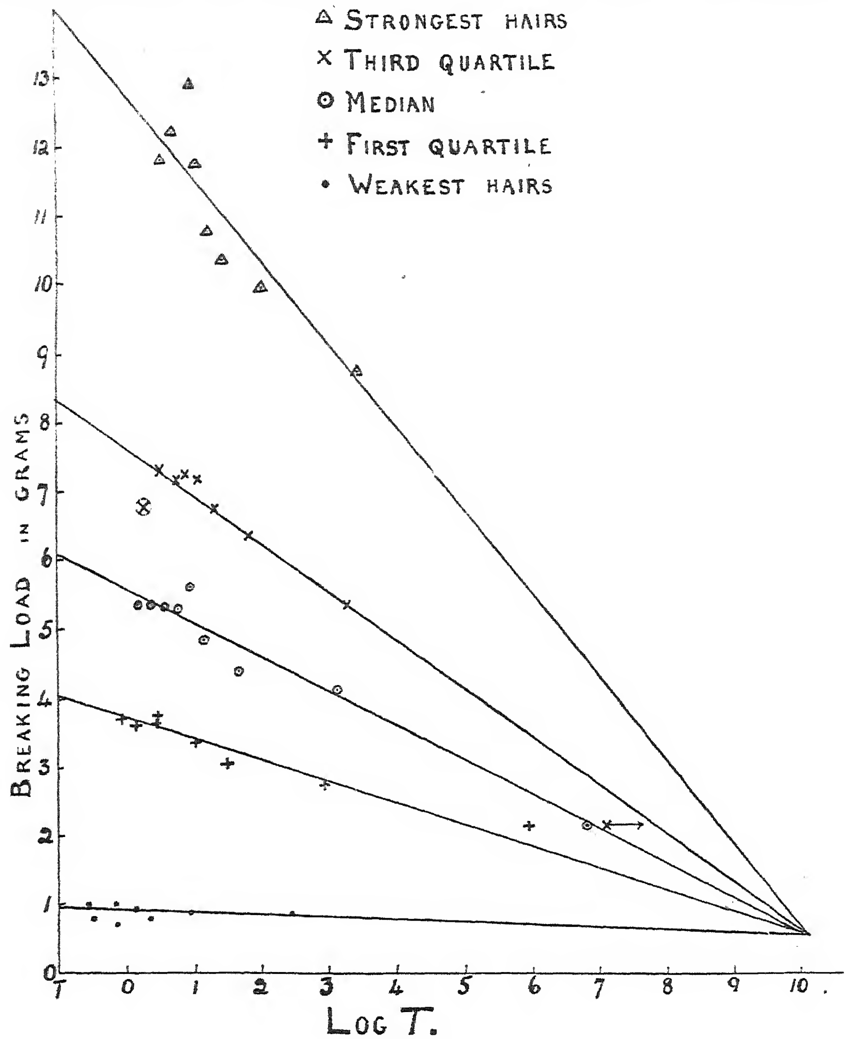

FIG. 4

by the lowest two lines of Table III. The points of convergence were found analytically and the centre of the ten was (F=0·58±0·16, log T=10·1). Of the ten points of convergence, two only were at negative values of F and these were given by the steepest lines; five lie between 0·7 and 0·8 gram and eight above 0·5 gram.

*As the rate of loading is measured with an error negligible compared with that of the determination of F, the condition for the best straight line is that $(\Delta F)^2+(\Delta \log F)^2$ or $(\Delta F)^2\left\{1+\left(\frac{\Delta \log F}{\Delta F}\right)^2\right\}$ be a minimum. The expression in brackets is so near unity and varies so little that this is indistinguishable from the condition that $(\Delta F)^2$ should be a minimum.

On Fig. 4 the points are shown fitted by a pencil of lines through the mean point of convergence and these give a fit scarcely less exact than the lines drawn through each set of points independently. The equation of the pencil is—

$$F - 0{\cdot}58 = 0{\cdot}11\, F_1\, (10{\cdot}1 - \log T).$$

where F_1 is the strength when $\log T$ is unity, *i.e.* for a time of break of 10 seconds.

The question whether the point of convergence is at a positive value of strength is of some physical interest. The value is too small to affect appreciably the large standard deviations and the most sensitive test is to see whether the weakest hairs are affected less in proportion than the strongest. As the single values are liable to considerable variation, the best straight lines were drawn through the mean values of the weakest ten and the strongest ten hairs. These meet at the value +0·818 gram and the effect is most probably real.

The results given on Table I. (A–D) were also plotted against $\log T$ and fitted with the least square line, with the following results—

Table IV.

Logarithmic Relation for Mean Breaking Loads.

Cotton	Mean F	Mean $\log T$	Slope $-dF/d\log T$
Sakel	5·14 ...	1·10 ...	0·504=0·097 F_1
Merc. Sea Island ...	7·92 ...	1·76 ...	1·110=0·127 F_1
Peruvian	8·57 ...	1·09 ...	0·861=0·100 F_1
Durango	5·0 ...	0·76 ...	0·945=0·197 F_1

Of these the last two are not so exactly defined by range of speeds as the first. For practical interpolation and for comparing results at different speeds, the following formula may be used—

$$F = F_1\, (1{\cdot}1 - 0{\cdot}1 \log T).$$

The Physical Nature of the Effect

The study of elastic imperfection goes back into the early part of last century and a great deal of work and of controversy have centered round its many forms. While avoiding the more controversial aspects, it is possible to relate this effect on breaking load with other effects of a simpler nature.

Strains—that is changes of shape and dimensions under stress, in particular extensions—may be divided into three classes, more or less definitely distinguishable. (1) *Elastic strains.* These are proportional to the stress, independent of time or past history, and disappear with the stress. Small strains in crystals and metals are elastic. (2) *"Epibolic" strains.* These produce the phenomena called "elastic after-effect." The strain increases with time but at a decreasing rate, attaining a final equilibrium, and eventually disappears, or decreases gradually to a small value, after removal of stress. These are involved in the stretching of wool fibres[7] and in the time decrease of couple in threads under moderate twist.[6] (3) *Ductile strains.* Semi-viscous flow proceeding indefinitely with time; irreversible, leading to attenuation and rupture.

The relative importance of the three types varies with the nature of the material, the intensity of the stress and its duration. At one limit, a perfectly brittle body will break under a purely elastic strain without any time effect on the breaking stress, at the other a semi-viscous material like pitch will eventually break under its own weight. In a material such as cotton, where the three types are appreciable, the proportion of each in a given

strain depends on the rate at which the strain has been produced and its duration.

The discussion is simplified if the breaking strain be regarded as constant, independent of time effect. A slight variation—and it is certainly much less than that of breaking load—would not affect the following argument and none could be found in yarns. The greatest stress which might be produced by the breaking strain would be found when this was applied so rapidly that no time effects could occur and would correspond to purely elastic strain.

On the other hand, a lower limit to the breaking load is set by the loads which cause only elastic and epibolic strains, when the hair undergoes an immediate extension followed by an increase at an ever lessening rate till a final equilibrium is attained. Collins[2] shows that an equilibrium is thus attained under appreciable loads, 0·5 gram, even on hairs under water.

It is thus clear that the logarithmic law cannot have any significance beyond an approximate description of the effect over the range capable of experimental study. Alternative expressions are capable of reproducing the two limits demanded by physical considerations and imitating the intermediate range perhaps more exactly, but the observations have not that degree of accuracy which would justify discriminating in favour of a more complicated formula.

Other forms of elastic imperfection can be measured more accurately, that closest to the present subject being the decrease in tension at constant extension. The variation of breaking load may be regarded as the decrease of tension with time in a hair stretched to just below the breaking point and held at constant length. The history is somewhat different, but this difference is the same for all rates of loading and should not alter the form of the curve greatly.

Trouton and Rankine[5] have found the load-time relation which keeps a lead wire at constant extension, and express it as—

$$F=c-a\log(T+b)$$

where F is the load at time T, c, a, and b are constants. This is precisely the relation used above to describe the breaking load effect.

The decrease of stress at constant strain can be measured still more accurately under twist, another form of the same physical effect. It has already been found[6] that the couple (C) in twisted cotton hairs is given by an expression—

$$C=c+ae^{-\beta T^{\frac{1}{3}}}$$

This expresses the physical fact of upper and lower limits, which exist in all three forms of the effect, and the data given by Trouton and Rankine have been fitted very accurately by this formula, but it is less elastic than the logarithmic expression and is accurate only for moderate or "epibolic" strains. The general similarity of the curves illustrates the unity of the effect and the behaviour under lower strains provides more accurate data for theories on the nature of elastic imperfection which, as a simple fact, can be regarded as the explanation of this variation of breaking load with rate of loading.

The relations of Fig. 4 indicate that in a batch of cotton of similar origin the strong hairs are more affected than the weak ones. Such a converging pencil would be given by a batch of similar tubes of very thin elastic material

coated internally to varying thicknesses with a stiff plastic substance. It is generally known that thin filaments are proportionally stronger and more elastic than thick ones, the surface layer than internal layers. The figure thus finds a natural explanation if the strength of the cotton hair be regarded as due to two elements, an outer layer relatively more elastic and constant with a varying amount of internal thickening of more imperfect tensile elasticity.

The greater effect on the mercerised Sea Island hairs may be due to a weakening of the outer layer. As the other two varieties were not tested below 0·10 gram per second, their slopes are not sufficiently well defined to correlate with other characteristics.

10—A NEW METHOD FOR THE ESTIMATION OF ALKALI WITH SPECIAL APPLICATION TO WOOL

By H. R. Hirst and A. T. King

SUMMARY

It is shown that the accurate estimation of total alkali in wool, which is of great importance for research purposes and for the investigation of faults, is not possible with any of the existing analytical methods.

A new method has been devised, depending essentially on the fact that wool placed in water containing terephthalic acid in suspension yields up the whole of the alkali contained in it into solution as sodium terephthalate. This solution can then be estimated by either gravimetric or volumetric methods, which are described in detail.

Using this method it is shown that a measured quantity of alkali, whether as caustic soda, sodium carbonate, or soap, added to wool, can be quantitatively recovered. A convenient and accurate method is thus available for the estimation of the total alkali in wool.

Thus by this method in conjunction with that for estimating soap already published (*J. Text. Inst.*, 1922, **13**, 143), the amounts of alkali present as soap and sorbed alkali respectively can be conveniently and accurately ascertained.

INTRODUCTION

We have previously shown in private reports (Nos. 16, 22, 23, 24, and 25) the importance of estimating the amount of alkali present in wool and fabrics, and have dealt with certain injurious effects which may arise if the amount is not controlled or is unequally distributed. In order to obtain more complete information, not only of the amount of alkali, but also the form in which it is present, we have had to devise more reliable methods of analysis than those previously available. A previous paper (Hirst, *J Text. Inst.*, 1922, **13**, 143) describes a method for the estimation of soap on wool, but the method described below goes further and gives a determination of the total alkali present. Thus the two methods give a closer insight into the mode of distribution of alkali in wool.

The method is suitable for wider application in analysis.

THE DIFFICULTY OF REMOVING ALKALI FROM WOOL

The estimation of alkali, and also of acid, in wool is by no means simple, on account of the special properties of wool itself, which as is well known readily absorbs these reagents. Consequently ordinary methods of titration carried out in presence of the wool are very laborious and uncertain. Again, alkali is held so tenaciously by the wool that simple washing with water never completely removes it. It is certainly not practicable to obtain neutral* wool by this method.

*We use the term "neutral wool" to indicate absence of foreign acid or alkali, and not as a statement that wool entirely freed from such is in itself strictly neutral in chemical character. The conception of the "isoelectric point" of proteins, in general, due to Hardy (*Proc. Roy. Soc.*, 1900, **66**, 110), as the point of maximum instability (or most rapid coagulation) of the colloid hydrosol, has been shown by Loeb ("Proteins and the Theory of Chemical Behaviour," 1922) to be of fundamental importance in relation to a number of specific properties of gelatin. There are many respects in which wool resembles gelatin, and it can be reasonably assumed that there is a definite iso-electric point for wool, as is the case with gelatin. Loeb's researches have shown that with pure gelatin the acid side of its amphoteric character slightly predominates, its *p*H value being 4·7, and that at this (iso-electric) point, the gelatin shows a minimum value for osmotic pressure, specific conductivity, viscosity and, notably, swelling. The iso-electric point of wool substance, which according to Speakman (*J. Soc. Dyers and Col.*, 1925, **41**, 176) is in the neighbourhood of 4·8, is thus of much practical as well as scientific interest.

Investigators working on the sorption of acids and dyestuffs by wool have employed various methods for purifying the wool. In our experience the best method for obtaining wool closely approximating to a strictly neutral condition is to acidise with hydrochloric acid, remove soap acids and other fatty impurities by alcohol-ether extractions, make slightly alkaline with aqueous ammonia, rinse well in distilled water, and dry by gentle heat or in vacuo over sulphuric acid.

The ordinary analytical methods remove soap and fatty acid, and a portion of the alkali present in scoured wool, but there always remains some alkali which is not removed from the wool. This incompleteness of extraction is well illustrated by the two examples below.

(1) *Addition of Caustic Soda to Wool*—A sample of approximately neutral cloth weighing 14·85 grams was treated with 9·2 cc. $N/10$ caustic soda solution diluted with absolute alcohol in sufficient quantity just to wet the cloth. The material was dried in vacuo and then extracted in a soxhlet apparatus with alcohol. Titration of the alkali contained in the alcohol extract gave only 5% of the alkali originally added. Washing four times in hot water and six times in cold, extracted in all a further 48·4%, giving a total of 53·4% recovered.

(2) *Addition of Soap to Wool*—A sample of cloth was impregnated with neutral soap solution (prepared from Kahlbaum's pure oleic acid and the exact equivalent of caustic soda) in quantity just sufficient to be soaked up and equal to 1·14% of soap on the weight of wool. The sample was divided and analysed in two ways—

(*a*) Alcohol extraction followed by repeated water extraction.

	Alkali equivalent to sodium oleate	Fatty acid equivalent to sodium oleate
% Removed by alcohol ...	42·8	99·5
,, water	46·2	0·0
Total	89·0	99·5

(*b*) Repeated water extraction followed by alcohol extraction.

	Alkali equivalent to sodium oleate	Fatty acid equivalent to sodium oleate
% Removed by water	69·0	36·9
,, alcohol ...	16·0	55·6
Total	85·0	92·5

These analyses provide further evidence of the fact that soap left on wool after scouring is present partly as acid soap and partly as alkali sorbed by the wool, and are in accordance with those previously obtained (*loc. cit.*) and with the general conclusions on sorption of soap (see King, *J. Text. Inst.*, 1922, **13**, 127). It will be observed that method (*a*) is the more accurate procedure for obtaining the fatty acid portion, but that neither is efficient as regards the alkali estimation.

Alkali by Titration—Regarding (*a*), a more complete return of the residual alkali is obtained after alcohol extraction by warming the wool in neutral distilled water, and titrating with standard acid in presence of a suitable indicator, such as Phenol Red or phenolphthalein. The titration is continued cautiously with constant stirring and warming from time to time until the indicator shows a permanent change.

This method of titration is interesting in itself, addition of acid to a point of apparent neutrality being followed by a discharge of alkali from the wool

so that the liquor again becomes alkaline. This gradually becomes slower and less marked until the point of actual neutrality is reached. The alkali sorbed by the wool is thus only slowly removed even in presence of very dilute acid solutions.

BEHAVIOUR OF INDICATORS IN TITRATIONS IN PRESENCE OF WOOL

The above described method gives reasonably good results where soap has been previously removed by alcohol extraction, and only sorbed alkali is present in the wool, but it is extremely slow and the final removal of the alkali is always somewhat in doubt.

Further, if soap is present erroneous results are obtained. With indicators whose range is on the alkaline side of neutrality, such as Phenol Red and phenolphthalein, the change point appears while acid soap is still present undecomposed, both acid soap and free fatty acid giving an acid reaction towards these indicators. Thus for a given amount of total alkali in the wool the value obtained will vary with the amount of fatty acid present, and will be somewhat higher than the sorbed alkali but lower than the total alkali present. Also the sensitiveness of such indicators to carbon dioxide in the air not only makes the end-point itself difficult to ascertain, but alters the value of the alkali content found, according to the extent to which it has been carbonated by exposure. Boiling out the carbon dioxide adds to the uncertainty of the result owing to risk of forming reactive products from the wool itself.

On the other hand, the use of indicators not sensitive to carbon dioxide whose change points are on the acid side of neutrality, is quite impracticable in the presence of wool, even if only alkali in caustic form is present. Even with Brom Cresol Purple (*p*H 5·2–6·8) considerable excess of acid has to be added before the indicator becomes permanently changed. The indicator registers the acidity of the solution in equilibrium with wool, and as wool absorbs practically all the acid from dilute solution, much additional acid beyond that required for neutralisation must be added before the residual solution reaches a *p*H value acid enough to affect the indicator.

QUANTITATIVE REMOVAL OF TOTAL ALKALI

There is room therefore for a method which will remove quantitatively and reasonably quickly the total alkali present, and a number of experiments have been made with this end in view.

(1) Attempted Removal as Ammonia

Experiments were made to ascertain if the alkali in the wool would give a quantitative yield of ammonia on boiling the wool in water containing a slight excess of ammonium salt.

Blank experiments showed that alkali in similarly dilute solution, whether as caustic soda, carbonate, or as soap, gave a quantitative yield, but when the experiments were repeated in contact with wool, other volatile alkaline products from the decomposition of the wool itself accompanied the ammonia formed in the main reaction. The extent to which these secondary effects occurred was much less when the distillation was carried out at 40° C. under diminished pressure, but the results were uncertain. Various amides were tried in place of ammonium salts, also with unsatisfactory results, and the method was abandoned.

(2) Removal as Sodium Terephthalate

Though acids and alkalis are readily sorbed by wool, with neutral salts the sorption effect, if it occurs at all, is negligibly small. Thus conversion of the alkali to sodium chloride, for example, would allow of its complete removal from the wool with relatively few washings, but the quantitative estimation of sodium salts is inconvenient for routine tests.

Experiments on the estimation of sulphuric acid in wool* showed that quantitative results could be obtained by conversion into sulphate by means of a carbonate in suspension, *e.g.*, magnesium carbonate and estimation as barium sulphate.

The same principles can be employed for estimating alkali by using a sparingly soluble acid which forms a soluble sodium salt. Acids suitable for this purpose must be solid, easily filterable, and practically insoluble in water, and give alkali salts which are readily soluble in and not appreciably hydrolysed by water. These considerations rule out a large number of acids, including the higher fatty acids. Lauric acid, for example, meets all but the last, but its sodium salt is hydrolysed by water and exhibits the characteristic behaviour of soaps in general of giving up alkali to the wool, with deposition of acid soap on the fibre.

After numerous trials a material suitable from every experimental standpoint was found in terephthalic acid. Chemically, this acid is distinctly stronger than the soap acids and readily decomposes soap, yet its solubility is very slight, its saturated aqueous solution being, in fact, alkaline to Brom Phenol Blue and Methyl Orange, though acid to all indicators whose change points are at pH values greater than 4·5. At 20° C. 1 litre of water dissolves 0·0168 gr. of terephthalic acid, less than 2/1000%. On the other hand, its sodium salt is readily soluble in water, and unlike soap solution, is not decomposed by carbon dioxide. Prepared by adding the acid with shaking to caustic soda until a small permanent excess remains, and then filtering, the solution is just acid (yellowish-green) to Brom Thymol Blue. The principle of the method will be clear from the following equations.

$$2NaOH + C_6H_4(COOH)_2 = 2H_2O + C_6H_4(COONa)_2 \quad . \; . \; . \; A$$

(Caustic soda+terephthalic acid=water+sodium terephthalate.)

$$Na_2CO_3 + C_6H_4(COOH)_2 = 2H_2O + CO_2 + C_6H_4(COONa)_2 \quad . \; . \; B$$

(Carbonate of soda+terephthalic acid=water+carbon dioxide+sodium terephthalate.)

$$2(C_{17}H_{34}COONa) + C_6H_4(COOH)_2 = 2(C_{17}H_{34}COOH) + C_6H_4(COONa)_2 \quad . \; . \; C$$

(Soda soap+terephthalic acid=fatty acid+sodium terephthalate.)

The whole of the combined alkali is thus converted into the equivalent quantity of sodium terephthalate. This can be conveniently rinsed off without handling with the fingers, in a Buchner funnel, or for larger samples by means of a small meat press, adapted to the purpose by being lined with vitralite and fitted with perforated discs of hardite.

Gravimetric Estimation of Alkali

The weight of terephthalic acid obtained by decomposing the filtered liquid with dilute acid is always found to be somewhat greater than corresponds to the quantity of acid which should theoretically be dissolved by the alkali present, and the results are always too high. This is presumably due

*See contribution on "The Estimation of Acid" (following item).

to the formation of a small quantity of acid sodium terephthalate, in addition to the main product, di-sodium terephthalate, represented in the equation above.

Example—10 grams of carefully neutralised wool were treated with standard caustic soda equal to 50 cc. $N/10$ NaOH in 250 cc. of water. After standing an hour, about 1 gram of purified terephthalic acid was added, and the beaker and contents maintained at 50° for two hours with occasional stirring. The wool was well pressed* and rinsed, the united liquors amounting to about 600 cc. filtered from excess of terephthalic acid, and the filtrate precipitated with dilute sulphuric acid. The weight of the dried precipitate of terephthalic acid was 0·4718 gram, compared with 0·4150 gram theoretically obtainable from equation A, or 0·226% NaOH on the weight of the cloth compared with 0·20% actually added.

This method is reasonably good for use in special cases of dyed material which, owing to bleeding of colour, cannot be otherwise estimated, but for general use the more accurate volumetric method described below is to be preferred.

Volumetric Estimation

Terephthalic acid is conveniently adapted to volumetric estimations by using an indicator whose change point occurs at an acid concentration just above that of saturated terephthalic acid solution.

Brom Phenol Blue is admirably suited to this purpose. With a *p*H range of 3·0–4·6 (from yellow to bluish-purple) it gives a neutral grey tint at about *p*H 3·6. When daylight is not available, a "daylight lamp" is preferably used for matching. Methyl Orange has a similar range (*p*H 3·1–4·4), but the colour change is far less striking. On adding acid (previously standardised against alkali using Brom Phenol Blue as indicator) to a liquid containing terephthalic acid and sodium terephthalate, the indicator remains purple until the whole of the sodium terephthalate is converted to acid, when further addition of acid changes the indicator. Thus a measure of the terephthalic acid present as sodium salt, and hence of the alkali removed from the wool, is obtained. The treatment of the wool with terephthalic acid, followed by filtration and washing, is as previously described.

In practice we prefer to add to the liquors a known excess of standard acid and filter, and then titrate back with caustic soda, as the change point of the indicator is somewhat obscured by terephthalic acid in suspension. Alternatively, phenolphthalein or Phenol Red can be used for the back titration, subtracting from the alkali titre the volume equivalent to the small quantity of terephthalic acid dissolved in the filtrate. This is approximately 0·1 cc. $N/10$ NaOH per 100 cc. of filtrate. Standardising against Brom Phenol Blue is thereby obviated, but to avoid a large error it is essential to use an aliquot portion of the original liquor, and to keep the volume of the filtrate small.

It will be observed that *neither the excess of terephthalic acid added to the wool, nor any sorption of terephthalic acid by the wool which might take place, nor the slight solubility of terephthalic acid, nor any formation of mono sodium salt referred to above* affect the result by this method, the terephthalic acid merely acting as a vehicle, so to speak, for the alkali.

---

*For routine work it is simpler and sufficiently accurate to commence with a known volume of liquid and analyse an aliquot portion of the liquor.

On the other hand, sorption by the wool of any hydrolysis-caustic soda from the sodium terephthalate formed, after the manner of soda soaps or sodium salts of weak acids in general, would of course vitiate the result. Such action was unlikely in view of the neutral character of the sodium salt, but the point was carefully tested experimentally by leaving sodium terephthalate in contact with neutral wool immersed in water and recovering it in quantitative amount. Examples—

(A) *Sample of Purified Wool*—9·95 grams of the wool, with 0·4 gram of terephthalic acid and 200 cc. of water, were warmed in a beaker to 60°, and then allowed to stand four hours. Sulphuric acid equal to 50·78 cc. $N/10$ was then added to the separated liquors. The filtered solution required 49·62 cc. $N/10$ NaOH. Thus the alkali present in the cloth corresponds to 1·16 cc. $N/10$ NaOH, or 0·046% NaOH calculated on the weight of cloth.

(B) *Above Sample again Treated as before*—The titration difference in this case was 0·15 cc., equal to 0·006% NaOH on the cloth, from which the cloth may be considered neutral within the range of experimental error.

(C) *Alkali in a Scoured Worsted well Washed Off*—Two samples of 10 grams each were treated, one at ordinary temperature with 24 hours' standing, which gave 0·182% caustic soda on the cloth; the other at 60° C. for two hours, which gave 0·211%. This material was used in the experiments detailed below, the average value 0·196 being taken as the alkali content.

(D) *Addition of Caustic Soda*—10·02 grams of cloth were wetted out in 200 cc. of water, to which was added 24·6 cc. $N/10$ caustic soda. After standing some hours, 0·4 gram terephthalic acid was added, the temperature raised to 60°, and the beaker left to stand two hours. The volume of H_2SO_4 added to the separated liquors was 50·78 cc. $N/10$. The filtered solution required 21·60 $N/10$ NaOH. The excess of acid over total alkali added is thus 4·58 cc., which is equal to 0·182% NaOH, compared with 0·196% found in Ex. (C) as being originally present.

(E) *Addition of Sodium Carbonate*—10·07 grams of wool were allowed to stand with 25 cc. $N/10$ Na_2CO_3 in about 200 cc. water. Terephthalic acid (0·4 gram) was then added, and the beaker and contents left to stand overnight. The volume of sulphuric acid added was 50·78 cc. and the caustic soda required was 20·91 cc. $N/10$. Thus the excess acid over the total alkali added is 4·87 cc., showing 0·193% alkali originally present, compared with 0·196 in Ex. (C).

(F) *Addition of Soap Solution*—A 10·05 grams sample was soaked in a warm soap solution equal to 0·979% NaOH on the weight of cloth, followed by addition of terephthalic acid. $N/10$ sulphuric acid added, 50·78 cc. $N/10$ caustic soda required, 21·87 cc. The difference of 28·91 cc. is equal to 1·150% total caustic soda on the cloth. Subtracting 0·196% found in Ex. (C) gives 0·954% soap as caustic soda, compared with 0·979% actually added.

Thus the terephthalic acid method gives quantitative returns of the total alkali in wool, whether present as caustic soda, sodium carbonate, or soap.

CALCIUM SOAPS

The effect of calcium salts, such as calcium oleate and stearate, which might be present on wool, on the method of estimation of alkali was then investigated. An estimation of the solubility of precipitated calcium terephthalate gave 0.484 gram per litre of distilled water at 60° C., from which one may reasonably expect terephthalic acid to be capable of reacting

with calcium soaps. A 10 grams pattern of worsted cloth, as used in the previous experiments, was treated with a mixture of 24·04 cc. $N/10$ caustic soda (=0·962% NaOH on the wool) and 2 grams pure oleic acid. After warming and stirring, 25 cc. $N/10$ calcium chloride solution, sufficient to convert the whole of the soap into calcium soap, was added and allowed to stand for two hours. Then the alkali was estimated by terephthalic acid and the following analytical figures obtained—

Acid added, 48·24 cc. $N/10$.

Back titration required, 19·17 cc. $N/10$ NaOH.

The difference of 29·07 cc. is equivalent to—

Total alkali=1·163% NaOH.

Subtracting 0·196% NaOH originally on the cloth, this leaves 0·967% NaOH for the alkali added, compared with 0·962% actually employed.

Thus calcium soaps are included in this method of estimating total alkali. When these are present a separate estimation of the calcium is necessary.

Miss M. I. Hind has assisted in the estimations. We are also indebted to Mr. J. Barritt, B.Sc. for carrying out independent analyses to check the methods.

11—THE ESTIMATION OF SULPHURIC ACID IN WOOL

By H. R. Hirst and A. T. King

SUMMARY

Work on the effects of sulphuric and other acids on wool, from both the technical and pure research points of view, has hitherto been hampered by want of a method at once accurate and convenient, of determining the actual quantity of acid present in the wool.

This paper describes a novel method, which depends essentially on the observation that sodium terephthalate reacts quantitatively with sulphuric acid present in wool. The method is free from the various objections which are raised against the present methods.

INTRODUCTION

The amount of acid remaining in wool and fabric after commercial treatments, such as dyeing, carbonising, and stoving, is of importance both for research purposes and for the investigation of faults. For example, the acid retained by wool has a considerable effect on dyeing and, after dyeing, has an influence on its power to absorb moisture (British Research Association Report, No. 33), and is also obviously of practical influence in connection with apparent losses in weight after dyeing. Up to the present, however, there has been no reliable method of estimation available.

The usual method is to add to the wool a known volume of, say, $N/10$ ammonia, leave in a stoppered bottle, and pipette off a known volume, which is then titrated for the remaining ammonia. It has been recorded, however (Lloyd, *J. Soc. Dyers and Col.*, 1914, xxx., 12), that "sliver treated with very dilute ammonia slowly absorbs the alkali, this reaction taking place more quickly when warm," on account of which this "generally accepted method for estimating acid in wool and unions is unreliable."

There are no particulars in the literature as to the extent of sorption of ammonia by wool, and this subject is at present under an investigation which is not yet completed. It may, however, be stated here that ammonia is absorbed from $N/10$ solutions to the extent of about 0·25% on the weight of wool, which is equivalent to an error of 0·7% in the estimation of sulphuric acid, apart from irregular results to be expected from such a method.

Regarding the addition of a known excess of alkalis other than ammonia, *e.g.* caustic soda or carbonate of soda, which are absorbed by wool to a greater extent than is ammonia, still larger errors would of course result.

The ammonia method can be made reasonably accurate for technical purposes by introducing a correction factor to allow for the ammonia sorption, or by carrying out a blank on neutral wool, but not sufficiently so for research purposes, especially as varying results would in any case be obtained with varying quantities of soap acid on the fabric.

OTHER PUBLISHED METHODS

The equilibrium between wool and sulphuric acid solutions has been utilised (Woodmansey, *J. Soc. Dyers and Col.*, 1918, xxxiv., 172) to determine the amount of sulphuric acid in wool by steeping the sample in water and then estimating the strength of the solution. The percentage of acid in the wool can then be read off from a curve. This method, apart from its indirect character, takes no account of differences in the sorptive power for acids of wools of different origin, and wools which have been differently processed.

Woodmansey (*loc. cit.*) mentions boiling the cloth with a crystal of Iceland spar, weighed before and after the experiment, but without a satisfactory analytical result.

FAILURE OF TITRATION METHODS GENERALLY

Complete extraction of the acid from the wool by water and titration of the extracts is impracticable. Also the procedure of wetting out the wool in water and running in standard alkali is open to several objections. The titration has to proceed very slowly in the last stages owing to the slow diffusion of the acid from the wool, and the end point is always uncertain for reasons already discussed in detail in the foregoing paper, *i.e.*, that with indicators whose range is on the acid side of neutrality, titration is impossible, and with other indicators, presence of soap acids affects the result.

REMOVAL AS NEUTRAL SALT

Obviously the considerations regarding the relative ease of removal in the form of a neutral salt, with reference to removal of alkali, apply equally to the removal of sulphuric acid. We have obtained fairly satisfactory results gravimetrically by agitating the wool with precipitated calcium or magnesium carbonate, and estimating the soluble sulphate formed by filtering and precipitating as barium sulphate in the usual way. Hydrochloric acid in wool can be similarly estimated as silver chloride. The following is an example, using magnesium carbonate—

A 10 gram sample of wool was placed in distilled water containing 0·1197 gram H_2SO_4, heated to 60° C., and allowed to remain for 15 minutes; 1 gram of $MgCO_3$ was then added, and after standing overnight the sulphuric acid was estimated in the liquor and washings from the cloth by means of barium chloride. The amount of barium sulphate was equivalent to 0·1205 gram sulphuric acid. Another example gave 0·2410 gram, compared with 0·2396 gram added to the cloth.

Magnesium carbonate is preferable to calcium carbonate, but neither method is ideal. If any calcium sulphate is already on the cloth as a result of calcium soaps being present prior to the dyeing or carbonising, it is included in the analytical result. The magnesium carbonate method also returns any metallic sulphates as sulphuric acid.

TEREPHTHALIC ACID METHOD

We have found the terephthalic acid method of estimating alkali (as described above) to be equally well adapted to the estimation of sulphuric acid. Sulphuric acid is quantitatively removed from wool by contact with sodium terephthalate solution in accordance with the equation—

$$H_2SO_4 + C_6H_4(COONa)_2 = Na_2SO_4 + C_6H_4(COOH)_2.$$

A measured volume of standard sodium terephthalate solution is added to the sample wetted out in water, and the subsequent procedure is exactly as described in the preceding paper for estimating alkali in wool volumetrically. In this method no complications are introduced by the presence of soap acids, as these do not decompose sodium terephthalate. Nor do small quantities of calcium or magnesium sulphate interfere.

Example—10 grams cloth containing 0·21% NaOH was treated with 24·12 cc. $N/10$ H_2SO_4 for one hour. Then 58·24 cc. $N/10$ sodium terephthalate solution was added, and the cloth and liquor heated to 60° C.

and allowed to stand overnight. The solution was poured off, the cloth washed* and pressed several times, the united solutions filtered and then 48·24 cc. $N/10$ H_2SO_4 added, and the solution again filtered and titrated with $N/10$ NaOH, using Brom Phenol Blue as indicator, 7·64 cc. being required.

The alkali originally present in the cloth (0·21%) corresponds to 5·25 cc. $N/10$ caustic soda. Thus the total alkali is 58·24+7·64+5·25=71·13 cc., which after subtracting 48·24 cc. $N/10$ H_2SO_4, subsequently added, leaves 22·89 cc. for that initially added, compared with 24·12 actually used, or 1·12% H_2SO_4 on the cloth, compared with 1·18%. The method has been found in practice to give concordant results.

Equally good results are obtained either by heating the cloth in the sodium terephthalate solution to 60° C. for 15 minutes and allowing to stand for three hours before filtering, or allowing the solution to act cold overnight. With dyed wool or cloth it is often an advantage to perform the estimation cold, so as to avoid colouring the solution and masking the indicator. We find, however, that when estimating acid on material dyed with dyes which are readily stripped, the gravimetric method, using magnesium carbonate, is the more satisfactory.

ESTIMATION OF ACID IN DYEBATH AND IN WOOL AFTER DYEING

A piece of white worsted cloth, weighing 10 grams and containing 0·21% alkali as NaOH, was dyed with 3% Orange GG crystals (Cas.) previously purified, and 46·7 cc. of $N/10$ sulphuric (equal to 2·39% on the weight of the cloth) in 500 cc. water, boiling for one hour. The dyeing operation was carried out in a flask provided with an air condenser. The residual liquor, two wash waters from the cloth, and the cloth after washing were analysed separately by the sodium terephthalate method.

The dyebath gave H_2SO_4 equivalent to ...	4·66 cc.	$N/10$ H_2SO_4
The first wash water from cloth	1·80 cc.	,,
The second wash water from cloth	1·04 cc.	,,
The cloth after twice washing	23·85 cc.	,,
The total acid recovered is thus	31·35 cc.	,,
Which is equivalent to	0·1536 gram	H_2SO_4
The dye (equivalent=226) contains sodium equivalent to	0·065	,,
Alkali originally in cloth corresponds to ...	0·0257	,,
Acid accounted for	0·2443	,,
Compared with acid actually used	0·239	,,

This leaves 0·005 gram H_2SO_4 unaccounted for, which represents a total accumulated error of 2½%.

*For routine tests it is simpler and sufficiently accurate to analyse an aliquot portion of the liquor.

12—COMPARISON OF THE AFFINITY OF COTTON, WOOL, AND PARTICULARLY CELLULOSE ACETATE SILK FOR AZO COMPOUNDS (DYESTUFFS) CONTAINING SULPHONIC, CARBOXYL, ARSINIC, AND STIBINIC ACID GROUPS

By Archibald John Hall, B.Sc. (Lond.), F.I.C. and
Michel Ivan Aische, D.Sc. (St. Petersburg), Ph.D. (Reval).

(The Silver Springs Bleaching and Dyeing Co. Ltd.)

General experience and research (cf. R. Clavel, E.P.182,830 and 182,844; British Dyestuffs Corporation Ltd., A. G. Green, and H. K. Saunders, E.P. 200,873; The Silver Springs Bleaching and Dyeing Co. Ltd. and A. J. Hall, E.P.222,001) show that with few exceptions (cf. British Dyestuffs Corporation Ltd. and G. H. Frank, E.P.226,948), cellulose acetate artificial silk has little or no affinity for aromatic compounds containing one or more sulphonic acid groups. Since it is generally desirable to employ water-soluble dyestuffs for cotton, wool, and natural silk, a large proportion of these dyestuffs are prepared from components containing substituted sulphonic acid groups and are therefore unsuitable for the dyeing of cellulose acetate silk.

Almost all those dyestuffs now in use for dyeing cellulose acetate silk are insoluble in water and are employed in aqueous suspensions (cf. J. S. Wilson, *J. Soc. Dyers and Col.*, 1925, **41**, 169) or colloidal solutions (S.R.A. dyestuffs) prepared by means of such substances as Turkey-red oil, oleates, and naphthenates (cf. G. H. Ellis, *J. Soc. Dyers and Col.*, 1924, **40**, 285). The use of these dyestuffs for the production of shades fast to rubbing requires an alkaline dyebath and the presence of free acid precipitates insoluble fatty acids in the form of an objectionable scum.

In the dyeing of mixtures of cotton and cellulose acetate silk with two colours in one bath the use of an alkaline bath presents no difficulty, for although it must be remembered that cellulose acetate is much more readily hydrolysed by alkalis than by acids, most direct cotton dyestuffs have a good affinity for cotton in an alkaline bath. On the other hand, the dyeing of wool usually requires the use of an acid dyebath and this renders difficult the dyeing of mixtures of wool and cellulose acetate silk with two colours in one bath. There is thus a demand for dyestuffs which are easily water-soluble and whose application to cellulose acetate silk does not require the presence of soaps or other solubilising substances in the dyebath.

The affinity of cellulose acetate for aromatic compounds is decreased by the presence of substituted sulphonic acid, carboxyl and hydroxyl groups, the effect of these groups decreasing in the order named. For example, with the exception of a few aromatic azo dyestuffs containing a sulphonic acid group in the ortho position to the azo link (cf. British Dyestuffs Corporation Ltd. and G. H. Frank, E.P.226,948, L. B. Holliday & Co. Ltd., and A Young, E.P. 244,936), no dyestuffs containing sulphonic acid groups are suitable for dyeing cellulose acetate, whereas a number of suitable dyes containing carboxyl (cf. British Dyestuffs Corporation Ltd., J. Baddiley, J. Hill, and E. B. Anderson, E.P.202,157; British Dyestuffs Corporation Ltd., J. Baddiley, and W. W. Tatum, E.P.207,711) and hydroxyl

groups are known. The possibility that dyestuffs soluble in water by reason of the presence of substituted arsinic, $AsO(OH)_2$, or stibinic $SbO(OH)_2$ acid groups may be suitable for dyeing cellulose acetate silk from neutral or acid dyebaths has apparently been overlooked.

Azo compounds containing arsinic acid groups have been described previously (cf. Noelting, *Bull. Soc. Chim.*, 1916, **19**, iv, 361), but it is not believed that they have found application as dyestuffs although many of them could be produced at a reasonable cost.

In the course of other investigations an opportunity occurred for comparing the affinity of cellulose acetate silk (also cotton and wool) for a number of azo compounds containing sulphonic, carboxylic, arsinic, and stibinic acid substituted groups and of further ascertaining the possibility of utilising such organo-arsenic and antimony compounds for dyeing or otherwise treating cellulose acetate silk. The results of these investigations are summarised below.

For the purposes of these investigations the following azo dyestuffs were prepared in the form of sodium salts from their components by the usual processes of diazotisation and coupling.

Compounds containing Sulphonic Acid Groups

Prepared from Sulphanilic Acid.—Sodium salts of α-naphthol-azo-phenyl-4-sulphonic acid (dark purple slender plates; easily soluble in cold and hot water), β-naphthol-azo-phenyl-4-sulphonic acid (golden yellow needles; easily soluble in cold and hot water), phenol-azo-phenyl-4-sulphonic acid (golden yellow plates; easily soluble in cold and hot water), and salicylic acid-azo-phenyl-4-sulphonic acid (yellow powder; easily soluble in cold and hot water).

Compounds containing Carboxyl Acid Groups

Prepared from p-Amino-benzoic Acid.—Sodium salts of α-naphthol-azo-phenyl-4-carboxylic acid (dark red compact cubical crystals; easily soluble in cold and hot water), β-naphthol-azo-phenyl-4-carboxylic acid (red rosettes; easily soluble in cold and hot water), phenol-azo-phenyl-4-carboxylic acid (orange needles; easily soluble in cold and hot water), and salicylic acid-azo-phenyl-4-carboxylic acid (yellow microscopic needles; easily soluble in cold and hot water).

Compounds containing Arsinic Acid Groups

Prepared from p-Arsanilic Acid.—Sodium salts of α-naphthol-azo-phenyl-4-arsinic acid (red microscopic plates; difficultly soluble in cold, easily soluble in hot water), β-naphthol-azo-phenyl-4-arsinic acid (orange slender needles; easily soluble in cold and hot water), phenol-azo-phenyl-4-arsinic acid (orange plates; easily soluble in cold and hot water), and salicylic acid-azo-phenyl-4-arsinic acid (pale brown powder; easily soluble in cold and hot water. Free acid; yellow compact crystals; insoluble in cold and hot water).

Compounds containing Stibinic Acid Groups

Prepared from p-Stibanilic Acid.—Sodium salts of α-naphthol-azo-phenyl-4-stibinic acid (reddish-brown powder; easily soluble in cold and hot water), β-naphthol-azo-phenyl-4-stibinic acid (scarlet rosettes; difficultly soluble in cold and hot water), phenol-azo-phenyl-4-stibinic acid (orange compact needles; difficultly soluble in cold and hot water), and salicylic acid-azo-phenyl-4-stibinic acid (light brown powder; easily soluble in cold and hot water).

Table I.

Azo Dyestuff	Shades of Dyeings on: Wool	Cotton	Cellulose Acetate: *a* (Alkaline)	Cellulose Acetate: *b* (Acid)
α-Naphthol-azo-phenyl-4-sulphonic acid	Deep brown	Stained bluish-pink	Stained pink	—
β-Naphthol-azo-phenyl-4-sulphonic acid	Bright reddish-orange	Stained pink	Pale orange	—
Phenol-azo-phenyl-4-sulphonic acid	Bright yellow	Colourless	Colourless	—
Salicylic acid-azo-phenyl-4-sulphonic acid	Bright yellow	Colourless	Colourless	—
α-Naphthol-azo-phenyl-4-carboxylic acid	Yellowish-brown	Pale pink	Stained yellow	—
β-Naphthol-azo-phenyl-4-carboxylic acid	Bright scarlet	Pale orange	Pale orange	—
Phenol-azo-phenyl-4-carboxylic acid	Yellow	Colourless	Colourless	—
Salicylic acid-azo-phenyl-4-carboxylic acid	Dull yellow	Stained yellow	Colourless	—
α-Naphthol-azo-phenyl-4-arsinic acid	Dull yellowish-brown	Pale yellow	Colourless	Deep reddish-yellow
β-Naphthol-azo-phenyl-4-arsinic acid	Bright orange	Stained orange	Stained orange	Deep orange
Phenol-azo-phenyl-4-arsinic acid	Pale yellow	Colourless	Colourless	Yellow
Salicylic acid-azo-phenyl-4-arsinic acid	Dull yellow	Colourless	Colourless	Greenish-yellow
α-Naphthol-azo-phenyl-4-stibinic acid	Reddish-brown	Pale pink	Pale orange	Stained brown
β-Naphthol-azo-phenyl-4-stibinic acid	Yellowish-orange	Pale orange	Pale orange	Deep orange
Phenol-azo-phenyl-4-stibinic acid	Yellow	Pale yellow	Pale yellow	Stained yellow
Salicylic acid-azo-phenyl-4-stibinic acid	Yellow	Pale yellow	Colourless	Stained yellow

Comparison of the above azo compounds indicates that those containing stibinic acid groups are less soluble in water than the corresponding compounds containing arsinic acid groups.

Samples of cellulose acetate silk (Celanese) yarn, bleached cotton fabric and bleached wool yarn were dyed with 5%, 2%, and 2% shades respectively under the following conditions.

Conditions of Dyeing

Cellulose Acetate Silk Yarn.—(*a*) Alkaline. One gram of yarn was dyed for one hour at 65° to 70° C. in 30 cc. of a 0·2% solution of soap and ammonia, then rinsed thoroughly in warm water and dried.

(*b*) Acid. One gram of yarn was dyed for one hour in 30 cc. of dye liquor initially at 60° C., and containing 15% of Glauber's salt, the temperature being raised to 75° C. and 3% of sulphuric acid added during the first ¼-hour and the dyeing continued at 75° C. The dyed yarn was afterwards thoroughly washed in warm water and dried.

Bleached Cotton Fabric.—One gram of bleached cotton fabric was dyed for one hour in 30 cc. of dye liquor initially at 50° C., the temperature being raised to 90° C. during the first ¼-hour and maintained at 90° C. No assistants were employed. The dyed fabric was afterwards thoroughly rinsed in cold water and dried.

Wool Yarn.—Ten grams of bleached wool yarn were dyed for one hour in 300 cc. of dye liquor initially at 60° C. and containing 15% of Glaubers salt, the temperature being increased to 100° C. (approximately) within the first ¼-hour and maintained at 100° C. Exhaustion of the dye liquor was assisted by the addition of 3% of sulphuric acid within 15 minutes from the commencement of dyeing. The dyed wool was thoroughly washed in cold water and then dried.

Examination of the resulting dyeings yielded the results shown in Table I.

Subsequently, the fastness of the dyeings on cotton, wool, and cellulose acetate silk to boiling water and soap was determined under the following conditions and with the results shown in Table II.

Fastness to Boiling Water.—¼-gram of dyed material was immersed in 30 cc. of water at 99° to 100° C. for one hour, then rinsed in cold water and dried.

Fastness to Soap.—¼-gram of dyed material was immersed in 30 cc. of a 0·2% solution of soap and ammonia at 99° to 100° C. for one hour, then rinsed in cold water and dried.

In the case of cellulose acetate silk both tests for fastness were carried out at 75° C. instead of 100° C.

Fastness to Light.—The dyed materials were exposed for 540½ hours in a standard Fadeometer apparatus. Since six hours' exposure in a Fadeometer are about equal to one bright mid-summer day, the above period of exposure is considered equivalent to three months of bright summer days.

The different results obtained by dyeing cellulose acetate silk in alkaline and acid dyebaths was largely due to the fact that the azo arsenic and antimony compounds were soluble in the former and insoluble in the latter. Cellulose acetate silk treated in the acid dyebaths appeared to be superficially coloured and was readily decolorised by soaping, dyeings with α-naphthol-azo-phenyl-4-arsinic acid and salicylic acid-azo-phenyl-4-arsinic acid being exceptional.

Table II.

Azo Dyestuff		Fastness to Boiling Water	Fastness to Soap	Fastness to Light
α-Naphthol-azo-phenyl-4-sulphonic acid	C	Nearly decolorised	Nearly decolorised

			(b) Decolorised	

C=Cotton; W=Wool; CA(a)=Cellulose Acetate Silk dyed in Alkaline Bath; CA(b)=Cellulose Acetate Silk dyed in Acid Bath.

From these investigations the following conclusions are drawn—

(1) Cellulose acetate silk and cotton have but little, and wool considerable affinity for all the azo compounds described above.

All the dyeings on wool have approximately equally good fastness to boiling water but have little fastness to boiling soap.

Azo compounds containing sulphonic, carboxylic, and arsinic acid groups have approximately equal fastness to light, whereas azo compounds containing stibinic acid groups are considerably less fast.

(2) Azo compounds containing stibinic acid groups have a greater affinity than those corresponding compounds containing arsinic acid groups for cellulose acetate silk, but these differences cannot be correlated to differences in the solubilities of the azo compounds in water.

(3) Azo compounds containing β-naphthol have a greater affinity than compounds containing α-naphthol for cellulose acetate silk (this is supported by results obtained in other, unpublished, investigations).

(4) The differences shown in the affinities of phenol-azo-phenyl-4-stibinic acid and salicylic acid-azo-phenyl-4-stibinic acid agree with the general observation that cellulose acetate silk has a decreasing affinity for azo compounds containing carboxyl and hydroxyl groups.

(5) The affinity of cellulose acetate silk for azo compounds containing sulphonic, arsinic, stibinic, and carboxylic acid groups increases in the order named.

(6) Although none of the organo-azo-arsenic and antimony compounds described above are suitable as dyestuffs for cellulose acetate silk, it appears probable that azo compounds containing arsinic and stibinic acid groups capable of satisfactory application to this textile material could be prepared.

In conclusion, the authors express their thanks to The Silver Springs Bleaching and Dyeing Co. Ltd., Congleton, for facilities afforded in carrying investigations.

13—THE LITERATURE OF KERATIN (THE PRINCIPAL CONSTITUENT OF WOOL)

By J. Barritt

(British Research Association for the Woollen and Worsted Industries.)

INTRODUCTION

In a study of the literature of keratin, one is immediately impressed with the fact that for a satisfactory understanding of the subject a certain general knowledge of the properties and reactions of the proteins is essential. It is because of this fact that much of what follows deals with proteins in a general manner. In the literature it is often found that the term keratin is loosely applied to many of the degradation products of keratin, which is incorrect and misleading. Keratin (see below) is obtained from definite sources and in a definite manner, and as such is clearly defined and restricted. It is to be distinguished from gelatin* and other proteins of the scleroprotein class, to which class it belongs.

Keratin is the principal constituent of the epidermis, hair, nails, hoofs, horns, *wool*, feathers, skins of egg shells, &c. When any of these substances are treated in succession with boiling ether, alcohol, water and dilute acids, or successively with artificial gastric juice, artificial pancreatic juice, boiling alcohol and boiling ether, the insoluble residue retains the shape of the original tissue and is known as *keratin*.

THE ANALYSIS OF KERATIN

The product varies somewhat in character and composition with its origin, so that a number of allied substances are comprehended under the general name of keratin. The following table, quoted from Allen's Organic Analysis, viii., illustrates the composition of the "keratin" obtained from different sources.

*For the sake of clarity some of the distinctions between keratin and gelatin will be given here, and will be understood after reading subsequent subject matter.

Gelatin is negative to the following tests—(i.) Millons. (ii.) Adamkiewicz. (iii.) Xanthoproteic (sometimes faintly positive).

Keratin, on the other hand, gives a positive reaction to all these tests.

Gelatin will mix with water in all proportions, but under ordinary conditions of temperature and pressure this is not true of keratin (*e.g.* wool).

Gelatin contains no tryptophane, cystine, or tyrosine, but contains more glycine than any other protein except elastin. It also contains a large amount of proline and oxyproline.

Keratins are remarkable for containing more cystine than any of the other proteins, human hair containing 14%. Tyrosine is present in fair amount, and the leucine and glutamic acid content is high.

It may be remarked that gelatin and keratin (at least many keratins) are amphoteric and in the case of gelatin the iso-electric point is found to be at $p\mathrm{H}=4{\cdot}7$ (*i.e.* on the acid side).

Source of Keratin	Carbon C	Hydrogen H	Nitrogen N	Sulphur S	Oxygen O_2*	Authority

Tortoise shell ...	54·89	6·56	16·77	2·22	19·56	Mühle
Neuro-Keratin (brain)	56·99	7·53	13·15	1·87	20·46	Kühne and Chittenden

Bourquelot[1] gives the following limits of composition of keratoids so far as has been recorded at present—

Carbon	50·3 to 52·5%
Hydrogen	6·4 to 7·3%
Nitrogen	16·2 to 17·7%
Oxygen	20·7 to 25·0%
Sulphur	·7 to 5·0%

Among many interesting analyses recorded in the literature, the following, due to Abderhalden and Fuchs,[2] is of particular interest in so far as it shows that from the same animal the constituents in the keratin vary considerably with age.

	Hoof of Ox		Horn of Ox		Hoof of Horse
	1 yr. old	4 yrs. old	1 yr. old	4 yrs. old	
Dry residue	90·5	91·5	96·0	96·5	75·4
Ash	·14	·16	·22	·36	·45
†Melanin substance	·22	·12	1·65	·96	·9
‡Glutamic acid hydrochloride in ash-freed residue	18·0	16·8	13·8	12·9	18·2

From the above two tables one can see that keratin substance is of variable composition. The carbon and hydrogen are fairly constant, but the percentages of sulphur and oxygen vary within comparatively wide limits. It is of interest to note the variation due to varying age of the animal.

The Presence of Elements, other than Carbon, Hydrogen, Nitrogen, Sulphur, and Oxygen, in Keratin

Gautier[3] states that the proteins of the thyroid gland, which contain arsenic and iodine, exert an activating influence on the organisms and promote the renewal of tissues. They are, however, especially attracted by the organs of the ectodermis, the brain, and principally by the skin. The skin utilises these proteins for the growth of the hair and of the epidermis. In male individuals the arsenic and iodine are excreted from the system by

*Oxygen by difference.

†Melanin substance is a brownish-black residue formed on hydrolysis of almost all proteins.

‡Glutamic acid (see list of Hydrolysis Products of Proteins).

the falling out of the hair, the shedding of the horns, and the scaling of the uppermost layer of the skin. In female individuals the elements are excreted in a different form.

In a paper due to G. Bertrand,[4] the above work of Gautier in respect to arsenic is verified, the method involving complete oxidation with nitric acid. It is shown that arsenic is especially to be found in keratin substances.

The presence of arsenic in various wool samples has been studied by Thorpe.[4a] In almost (but not quite) all samples arsenic is found in small amounts. In all samples it was found that the white ends near the body contained less than the tips. The amount of arsenic usually ranged from ·005 to ·037 milligrams of arsenious oxide per gram of wool. It appears probable that arsenic is not an essential constituent of wool, but is easily introduced by arsenical sheep dips or internally (see Gautier above).

It is usually stated in the literature (*cf.* Mathews, Textile Fibres, 1924, p. 124) that in wool a small amount of mineral matter appears to be present as an essential constituent of the fibre itself. It is left as ash when wool is ignited and amounts in some samples to 1% and contains many elements other than carbon, nitrogen, hydrogen, oxygen, and sulphur, *e.g.* potassium, sodium, calcium, aluminium, iron, silicon, and phosphorus. Considering the variation in the amount of ash found, and also in view of the fact that almost all the above mentioned elements are to be found in the suint, it appears reasonable to suggest that many of the above elements are probably not essential constituents of wool keratin.

Buchtala[5] has shown that the keratin of the elephant epidermis contains considerable quantities of iron.

THE CONSTITUTION OF KERATIN

Keratin belongs chemically to that class of substances known as *proteins*, of which some forty or fifty natural ones are known to occur in both animals and plants, and are divided according to their origin, coagulability on heating, and other physical characteristics into a series of groups. This separation into groups is very arbitrary, and no real classification of proteins is possible, due to our insufficient knowledge of their chemical constitution. For a list of these groups reference may be made to any book relating to the subject, *e.g.* Monograph by Plimmer, "Constitution of the Proteins."

Almost all the proteins contain carbon, hydrogen, nitrogen, sulphur, and oxygen, and they possess the following elementary composition—

C	51—55%
H	7%
N	15—19%
S	·4 to 2·5%
O	20—30%

Keratin belongs to the scleroprotein group. This group consists of the following—Keratin (from hair, horn, feathers, egg membrane, &c.), collagen, gelatin, elastin, silk fibroins, and silk gelatin.

As illustrating the complexity* of the molecule, the formula of globin, the basis of hæmoglobin, as obtained from an analysis such as that given above, is given approximately as $C_{730}H_{1170}N_{190}S_3O_{210}$, this representing a lower limit.

*It is known that hæmoglobin contains iron, and analysis leads to the fact that assuming there to be only one atom of iron in the molecule, the molecular weight has a minimum value of about 16,600. This value is in agreement with those obtained from data on the combination of carbon dioxide and oxygen with hæmoglobin.

Investigations on the chemical constitution of the proteins have been carried on now for nearly a century, but it is only in recent years that the work of E. Fischer and his pupils has thrown any real light on their actual constitution. The main result of these investigations is that the protein molecule is built up of a number of amino acids belonging to four different series (see following list).

It is generally assumed that these amino acids are linked together in the protein molecule as in the polypeptides, by the union of the amino group of one molecule with the carboxyl group of another. Thus—

$$NH_2-\underset{}{\overset{R'}{\overset{|}{C}}}H-COOH+NH_2-\overset{R''}{\overset{|}{C}}H-COOH \longrightarrow NH_2-\overset{R'}{\overset{|}{C}}H-CO-NH-\overset{R''}{\overset{|}{C}}H-COOH+H_2O$$

represents the condensation of two amino acids. The formation of a protein may be represented—

$$NH_2-\overset{R'}{\overset{|}{C}}H-COOH+NH_2-\overset{R''}{\overset{|}{C}}H-COOH+\;.\;.\;.\;.\;.\;+NH_2-\overset{R^n}{\overset{|}{C}}H-COOH$$

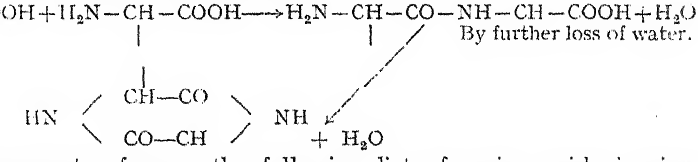
$$=\underbrace{NH_2-\overset{R'}{\overset{|}{C}}H-CONH-\overset{R''}{\overset{|}{C}}H-CO\;.\;.\;.\;.\;CO-NH-\overset{R^n}{\overset{|}{C}}H-COOH}_{\text{Protein Molecule.}}+(n-1)H_2O$$

In this equation R may represent a simple alkyl or aryl group, or a similar group, in which a hydrogen atom is substituted by an amino or a carboxyl group. This fact, coupled with the probable large value of "n," gives some indication of the complexity of the protein molecule.

The possibility of other types of grouping must be considered, and E. Fischer has suggested that piperazine groups may be present in the protein molecule.

Ring formation is easily accounted for by the elimination of water from a complex of two amino acid molecules, as follows—

$$H_2NCH-COOH+H_2N-CH-COOH \longrightarrow H_2N-CH-CO-NH-CH-COOH+H_2O$$



For subsequent reference the following list of amino acids is given. These acids, together with ammonia, are obtained in the hydrolysis of proteins, and most proteins contain all these amino acids or units in various proportions, but some proteins, *e.g.* gelatin, contain only fourteen or fifteen, and a few, such as salmine, are built up of three or four units, these being di-amino acids and histidine.

Fischer has succeeded in synthesising compounds built up of as many as eighteen amino acids, and some of the products obtained have shown properties very similar to many naturally occurring proteins.

It is known that many proteins can be hydrolysed to amino acids by use of various enzymes, and one of the best proofs that proteins are built up of amino acid complexes (*i.e.* polypeptides) is that furnished by Fischer of the action of enzymes upon the synthetical products. It was found that with the exception of pepsin the various enzymes of the body are quite capable of hydrolysing the polypeptides into amino acids.

HYDROLYSIS PRODUCTS OF PROTEINS

(A) Mono-aminocarboxylic Acids

Glycine, or amino acetic acid, $CH_2(NH_2){-}COOH$.

Alanine or α-aminopropionic acid, $CH_3{-}CH(NH_2){-}COOH$.

Valine or α-aminoisovaleric acid, $\begin{array}{l} CH_3\diagdown \\ \quad\; CH{-}CH(NH_2){-}COOH. \\ CH_3\diagup \end{array}$

Leucine or α-aminoisocaproic acid, $\begin{array}{l} CH_3\diagdown \\ \quad\; CH{-}CH_2{-}CH(NH_2){-}COOH. \\ CH_3\diagup \end{array}$

Caprine or α-aminocaproic acid, $CH_3CH_2CH_2CH_2CH(NH_2)COOH$,

Isoleucine or α-amino-β-methyl-β-ethyl propionic acid—

$$\begin{array}{l} CH_3\diagdown \\ \quad\; CH{-}CH(NH_2){-}COOH. \\ C_2H_5\diagup \end{array}$$

Phenylalanine or β-phenyl-α-aminopropionic acid—

$$C_6H_5{-}CH_2{-}CH(NH_2){-}COOH.$$

Tyrosine or β-*p*-hydroxyphenyl-α-aminopropionic acid—

$$(OH){-}C_6H_4{-}CH_2{-}CH(NH_2){-}COOH.$$

Serine or β-hydroxy-α-aminopropionic acid—

$$OH{-}CH_2{-}CH(NH_2){-}COOH.$$

Cystine, dicysteine or di-β-thio-α-aminopropionic acid—

$$HOOC{-}CH(NH_2){-}CH_2S{-}S{-}CH_2{-}CH(NH_2){-}COOH,$$

(B) Mono-aminodicarboxylic Acids

Aspartic acid or aminosuccinic acid, $\begin{array}{l} CH(NH_2){-}COOH \\ \;| \\ CH_2 \quad {-}COOH \end{array}$

Glutamic acid or α-aminoglutaric acid, $\begin{array}{l} CH_2{-}CH(NH_2){-}COOH \\ \;| \\ CH_2{-}COOH \end{array}$

(C) Diaminomonocarboxylic Acids

Arginine or α-amino-δ-guanidine valeric acid—

$$HN{=}C\begin{array}{l} \diagup NH_2 \\ \diagdown NH{-}CH_2{-}CH_2{-}CH_2{-}CH(NH_2){-}COOH \end{array}$$

Lysine or α-ε-diaminocaproic acid—

$$CH_2(NH_2){-}CH_2{-}CH_2{-}CH_2{-}CH(NH_2){-}COOH.$$

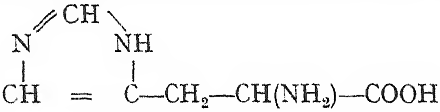
Ornithine or α-δ-diaminovaleric acid, $(H_2N)CH_2CH_2CH_2CH(NH_2)COOH$.

(D) Diamino-hydroxy-monocarboxylic Acid

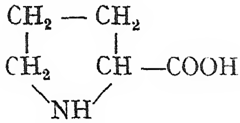
Caseinic acid or diaminotrihydroxy-dodeanic acid, $C_{11}H_{16}(OH)_3(NH_2)_2COOH$.

(E) Heterocyclic Compounds

Histidine or β-iminazole-α-aminopropionic acid, $C_6H_9O_2N_3$,—

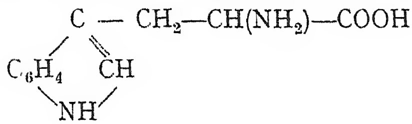


Proline or α-pyrolidine carboxylic acid,



Hydroxyproline or hydroxypyrolidinecarboxylic acid, $C_5H_9O_3N$.

Tryptophan or β-indole-α-aminopropionic acid, $C_{11}H_{12}O_2N_2$,—



Several of the above substances exist conjugated in the protein molecule in an optically active form.

The separation of a mixture of any or all of the above substances, *i.e.*, a mixture such as results from a protein hydrolysis, is a very complex and in many respects an unsatisfactory process.

Emil Fischer introduced (1901) a new method for the separation of these acids which depends on the fractional distillation *in vacuo* of their esters, and which is now commonly known as the ester method. The method, though not really quantitative, has enabled us to obtain a knowledge of some 70% of the total hydrolysis products, and has demonstrated that phenylalanine, serine, and alanine (see list of amino acids), are present in all proteins. The method also demonstrated the presence of two new compounds—proline and oxyproline.

With the exception of glycine, all the amino acids contained in proteins are optically active, and this further enhances the difficulty of synthesis.

The compound mentioned previously as synthesised by Fischer, if it had been found in nature, would have been described as a protein. Up to the present, however, no naturally occurring protein has been synthesised.

THE HYDROLYSIS OF THE PROTEINS

A brief account of the general methods employed in protein hydrolysis is given, almost all of which are directly applicable to the hydrolysis of keratin, which is considered in detail later.

Hydrolysis with Hydrochloric Acid

(i.) *Concentrated Acid*—The hydrolysis is carried out by heating the protein with three times its quantity of concentrated acid (density=1·19). It is boiled for from 6 to 24 hours, depending on the particular protein. The product is filtered and the acids are to be found in the solution.

(ii.) *Dilute Acid*—Van Slyke[6] has shown that hydrolysis may be equally well effected by boiling the protein with from 10 to 20 parts of 20%

hydrochloric acid from 20 to 50 hours. Van Slyke[7] has shown also that hydrolysis is usually effected using $3N$ acid in an autoclave at 150° C. (use thirty times as much acid as protein).

(iii.) *Alcoholic Hydrochloric Acid* has been used, but the results are not so good as when the aqueous acid is used.

Sulphuric Acid

Sulphuric acid of 30% strength is an effective agent, the amount used being six times the quantity of the protein and the boiling continued for about twenty-four hours.

Hydrolysis with Hydrofluoric Acid

Hugounenq and Morel[8] have employed hydrofluoric acid and find that the results depend on the strength of the acid; the stronger the acid the greater is the amount of complex polypeptides. Prolonged boiling with dilute acid is required to effect complete hydrolysis.

Hydrolysis with Alkalis

Abderhalden and his co-workers[9] have compared the hydrolysis by acids and alkalis, using hydrochloric acid, 25% sulphuric acid, 25% sodium hydroxide and saturated baryta. Proteins are not generally hydrolysed by boiling with alkali, and if used alkali will destroy arginine and cystine. Abderhalden and Brahm[10] found, however, that a body obtained from silk was resistant to hydrolysis by acid, but could be completely hydrolysed by alkali.

Hydrolysis by Enzymes

Hydrolysis by the action of proteoclastic enzymes is never complete. Fischer and Abderhalden[11] have shown that the portion unattacked contains all the phenylalanine and proline present in the protein molecule. The enzyme hydrolysis, however, is of use for the discovery of new units in the protein molecule.

THE REACTIONS OF KERATIN

The colour reactions of keratin and of proteins in general are very characteristic.

(i.) Solid proteins are coloured deep yellow by a solution of iodine.

(ii.) Treatment with nitric acid (density=1·2 to 1·25) gives a bright yellow colour. The coloration is due to the formation of a yellow substance of indefinite composition, known as xanthoproteic acid. This latter is soluble in ammonium hydroxide and fixed alkali hydroxides with orange red or brownish-red colour. The reaction is probably due to presence of a radical containing the benzene ring. With gelatin this reaction is negative or very faint.

(iii.) When a solution of a protein is treated with Millons' reagent,* a white precipitate forms which turns brick red on boiling, and the supernatant liquid becomes red after a time. Solid proteins become red when boiled with Millons' reagent. Gelatin yields reaction faintly or not at all. The reaction is due to the presence of tyrosine groups, which are absent in gelatin and protamines. The reaction does not take place in presence of sodium chloride.

**Preparation of the Reagent*—Treat mercury with an equal weight of nitric acid (density=1·4) when the action slackens, apply gentle heat till complete solution is effected. Dilute solution with twice its volume of water, allow to stand for some hours, and decant from deposit which forms. The liquid thus prepared is a solution of mercurous nitrate, holding nitrous acid in solution to the presence of which its action is partly due.

(iv.) The *Biuret* or *Piotrouski* test—If a few drops of a dilute copper sulphate solution be added to the solution of an albumin or globulin, a precipitate of copper albuminate will be produced. On the addition of an excess of sodium or potassium hydroxide to the liquid, the precipitate will dissolve with production of a fine violet coloration. Using ammonium hydroxide, a blue coloration is produced. M. Becke[12] has used this reaction for determining the degree of action on wool of various agents employed in mordanting, dyeing, &c.

(v.) The *Adamkievicz* reaction—This colour reaction is due to the presence of the tryptophan group. As applied by Hopkins and Cole, the test consists in treating the protein solution with a few drops of a dilute solution of glyoxylic acid, and then gradually adding one volume of concentrated sulphuric acid. If tryptophan be present, a reddish-violet colour is produced.

Numerous other colour reactions depending upon formation of tryptophan are known. A positive reaction is obtained with all proteins except gelatine and the protamines, though cylcopterine, a protamine, however, contains tryptophan groups, and consequently gives a positive reaction.

(vi.) *Molisch's* reaction—A violet colour is produced on adding strong sulphuric acid to a protein solution containing an alcoholic solution of α-naphthol. This reaction is given by all proteins which contain carbohydrate complexes and depends upon the production of furfurol by the action of the mineral acid.

THE DEGRADATION PRODUCTS OF KERATIN

Two main lines of attack have been directed on the keratin molecule, namely—

(i.) Hydrolysis.
(ii.) Mild oxidation.

The various resulting products have been isolated, characterised, and in some cases quantitative results have been obtained. The yields of various products differ greatly according to the exact conditions employed, and nothing but general agreement as to the presence of certain degradation products is to be found in a search of the literature. This difficulty is further apparent when one considers the immense number of "keratins" (or keratin substances) which have been used by different investigators.

The Action of Water

In a series of papers, Heiduschka and Komm[13] have investigated the action of water on horn clippings heated in sealed vessels, and also the action of heat on horn clippings at atmospheric pressure, in a vacuum and in sealed vessels. The temperature of initial partial degradation varies with the time of heating and the conditions of the experiment, and among the volatile products are sulphuretted hydrogen, ammonia, and sulphur compounds.

Using the iron method of Siegfried, a peptone has been isolated from the products of the partial hydrolysis of horn, having the empirical formula $C_{11}H_{20}O_5N_3$ and $[\alpha]_{20}^{D} = -15{\cdot}5°$ (approx.).

The proteoses obtained from the partial hydrolysis of horn have been fractionated, and the solubilities and reactions of the various hetero-keratoses, protokeratoses, and deuterokeratoses investigated.

R. Bauer[14] has shown that when keratin obtained from horn shavings is heated with water in sealed tubes at 150° C. for 24 hours, considerable amounts of sulphuretted hydrogen and a second volatile sulphur compound, presumably methyl mercaptan, are formed (*cf.* above), and the solution contains *two* compounds corresponding with Neumeister's[45] atmidalbumin and atmidalbumose, which Bauer terms atmidkeratin and atmidkeratose. They are readily obtained by concentrating the solution and saturating it with powdered sodium chloride, when atmidkeratin is precipitated. The filtrate from this precipitate, on treatment with hydrochloric acid saturated with sodium chloride, yields first a mixture of the two compounds and then atmidkeratose. The compounds are slowly acted upon by pepsin and trypsin.*

Hydrolysis of Keratins, using Dilute Acids

A fair amount of work appears to have been carried out on the hydrolysis of keratin using dilute acids. The general conclusion which may at once be drawn is that keratin is a mixture of proteins. This is evident when the large number of hydrolysis products is noted, and also from the fact that from some types of keratin, products are obtained which are not obtained, at least under conditions yet employed, from other types of keratin.

Buchtala[15] has hydrolysed the keratin from white human hair and obtained the following products (*see* "List of Hydrolysis Products" for structure)—

Glycine	9·12%†	Phenylalanine ...	·62%
Alanine	6·88%†	Tyrosine	3·3 %
Leucine	12·12%	Cystine	11·55%†
Glutamic acid	8·0%		

Buchtala[16] has also hydrolysed the keratin obtained from the scales of the *Manis japonica* (a species of ant eater), and also that from snake skins. The general result of the investigation may be taken to show that the nitrogen content of these various keratins is fairly constant, but they differ widely in the proportions of the individual amino acids which they contain. Snake skin keratin contains a high proportion of tyrosine and leucine. Keratin of the scales of the *Manis japonica* yields an unusually large proportion of alanine and tyrosine.

Abderhalden[17] and co-workers have worked on keratins from horns and wool of sheep, from horse hair, goose feathers, and hog bristles. None of the results agrees with the other, and the conclusion is that keratin is a mixture of proteins. The results obtained from 100 grams of ash-free, water-free, and melanin-free keratin, prepared from horse hair, on hydrolysis are—

Glycine	4·7 grams	Glutamic acid	3·7 grams
Alanine	1·5 ,,	Tyrosine	3·2 ,,
Aminovaleric acid ...	·9 ,,	Serine	·6 ,,
Leucine	7·1 ,,	Pyrolidine-2-carboxylic acid	3·4 ,,
Aspartic acid	·3 ,,		

*Compare Thorpe's "Dictionary" under keratin, where it is stated that "Keratin resists the action of pepsin and trypsin." Also Allen, vol. VIII., p. 676. "Keratin is not acted upon either by pepsin or trypsin."

The statement that keratin is not acted upon by pepsin is correct, but the second is probably erroneous, since keratoids undergo digestion in the small intestine, keratin having been used for coating pills intended to act on the small intestine.

†The amounts of cystine, glycine, and alanine are abnormally large, the general conclusion being that hair keratin closely resembles that from sheep's wool.

100 grams of ash-free and water-free keratin from goose feathers yielded on hydrolysis—

Glycine	2·6 grams	Aspartic acid	1·1 grams
Alanine	1·8 ,,	Tyrosine	3·6 ,,
Aminovaleric acid ...	0·5 ,,	Serine	·1 ,,
Leucine	8·0 ,,	Pyrolidine-2-carboxylic acid	3·5 ,,
Glutamic acid	2·3 ,,		

A promising method of attack upon the nature of the structure of the keratin complex has recently been made by Abderhalden and Komm[18] who have attempted a gentle decomposition of hog bristles. It would appear that only by a gradual breakdown and recognition of the earliest breakdown products can any real attempt be made upon the structure of the keratin complex. The experimental procedure was as follows—

(*a*) 400 grams of hog bristles were heated with 2,000 cc. 1% hydrochloric acid in an autoclave at 120° for five hours, the product neutralised with ammonium hydroxide, evaporated to dryness, mixed with sand, and extracted with ethyl acetate. The following were obtained from the extract—

d-Alanylglycine anhydride, m.p. 250° (decomp.);

Prolyl-leucine anhydride, m.p. 153° $[\alpha]_{20}^{D\circ} = -46{\cdot}3$ (in alcohol), (apparently partly racemised);

1-Prolyl-*d*-valine anhydride, m.p. 250°–252°; and

A compound, $C_{14}H_{23}O_3N_3$, of m.p. 180°–182°, which yields on hydrolysis, proline, leucine, and alanine, and is formed from these by loss of 3 molecules of water.

(*b*) Using 70% sulphuric acid as hydrolysis agent for seven days, the only pure compound isolated was—

1-leucylserine $[\alpha]_{20}^{D} = -44{\cdot}3$ (in water).

(*c*) From product of hydrolysis, using 70% H_2SO_4 for 14 days, a valyvaline, m.p. 255°–260° $[\alpha]_{20}^{D} = +3{\cdot}5°$ (in water), was obtained.

In both cases, however, other scission products were shown to be present.

Degradation Products Formed by Oxidation

Oxidation with Hydrogen Peroxide—Breinl and Baudisch[19] have heated keratin obtained from human hair with 30% hydrogen peroxide, and obtained the following products—

Sulphuric acid, nitric acid, sulphur, carbon dioxide, acetic acid, oxalic acid, succinic acid, acetaldehyde ammonia, and small amounts of amino acids.

Glycine, alanine, leucine, aspartic acid, and cystine are oxidised when heated with 30% hydrogen peroxide, yielding ammonia, carbon dioxide, aldehydes, and organic acids. Tyrosine is not oxidised. It appears that a milder treatment would have been very informative, as giving some idea of the initial break-down products. Mild oxidation, such as carried out in investigation of the structure of Balbiano's acid (Rothstein, Stevenson, and Thorpe[20]), or oxidation of terpene products, *e.g.* the successive oxidation of α-terpineol, giving eventually terpenylic acid. The use of potassium ferricyanide as a mild oxidising agent, Wallach,[44] does not appear to have been attempted (see H. D. Dakin[21]).

The State of Combination of Sulphur in Keratin

P. N. Raikow[22] has examined the action of phosphoric acid on wool and

not containing much grease, &c., and approximating to wool keratin) were placed in a stoppered bottle of 300 cc. capacity with phosphoric acid (sp. gr.=1·7). The wool becomes brown after 16 hours, and on removing the stopper a strong smell of sulphur dioxide is noticed. After two months, the contents of the bottle are changed to a dark brown, thick, homogeneous liquid, and evolve a very powerful odour of sulphur dioxide.

In the opinion of the author, this proves that part of the sulphur in keratin is combined directly with oxygen. Human hair behaves in much the same way, though the action is somewhat slower. One gram of each of the following substances, sulphuric acid, potassium methyl sulphate, sulphanilic acid, &c., allowed to remain ten days in stoppered bottles with 20 cc. of phosphoric acid, did not in any case evolve sulphur dioxide. The conclusion is reached that the sulphur in the keratin molecule (?) is not combined as a sulphate or sulphonic acid, but probably in a sulphite-like form.

A further paper on the above subject is due to Baudisch,[23] who has repeated the above work of Raikow using wool, and has substantiated his results. S. R. Trotman, E. R. Trotman, and R. W. Sutton,[23a] in a paper of recent date, have repeated the above experiment of Raikow with negative results, and further organic sulphides or mercaptans could not be obtained by the action of alkali on wool as stated by Chevreul. In addition (*cf.* above paper of Breinl and Baudisch), the oxidation of the sulphur to sulphur trioxide has been accomplished by using hydrogen peroxide. When, however, the wool is *first chlorinated*, no trace of sulphur dioxide is observed on treatment with phosphoric acid.*

The Oxidation of Keratin Sulphur and Cystine Sulphur by Potassium Permanganate

Lissizin,[24] in comparative experiments, has shown that a larger amount of sulphur is split off from cystine as sulphuric acid than from keratin (keratin prepared from hair). In the oxidation of keratin, the bulk of the sulphur remains in an organic combination soluble in water only, 10% being converted into sulphuric acid, whereas 47% of sulphur in cystine is converted to sulphuric acid.

In an earlier paper, using permanganate as oxidising agent, Lissizin[25] has shown that small quantities of azelaic acid are produced. From 240 grams of keratin, ·0468 grams of acid were obtained. (For further work on sulphur see section on wool keratin below.)

In a paper, "New Studies on Keratin," Unna and Godolety[26] describe a method of separation of keratin substances. They state, in agreement with all other work on the subject, that horn and similar substances, such as human epidermis, are not uniform in character, but can be separated by treatment with fuming nitric acid, or still better with sulphuric acid and hydrogen peroxide, into three constituents. The three constituents are designated Keratin A,† Keratin B, and soluble albuminoids.

Keratin A represents the most resistant and is not attacked by the strong acid nor by dilute alkali. It constitutes the epithelial cells, and was found

*It seems probable that during the process of chlorination we get oxidation of the "sulphite-like" groupings to sulphate-like groupings, and consequently the above result is to be expected. In other words, one effect at least of chlorination is oxidation.

†The use of the term "keratin" for the above oxidation and decomposition products is unjustifiable, when one considers the original meaning and significance attached to the word "keratin."

to contain on the average—C=53%, H=7%, S=1·75%, N=14%, and Ash=·6%.

Keratin B is precipitated from the acid solution by water and is soluble in dilute alkali, and contains about 5% less carbon than Keratin A. Horn contains about 6% Keratin A and 30% Keratin B. The per cent. of sulphur is not so high as is usually supposed to be the case.

USES OF KERATIN

The uses of keratin in the form of "wool," horn, &c., &c., are too widely known to require elaboration. Strictly speaking, they cannot be designated as keratin; they are keratin plus impurities. Keratin, as such, has been converted into useful products which can be used instead of casein for many purposes, and numerous patents have been taken out, *e.g.*—

French Pat. 360,895, 23rd Dec. 1905,[27] is as follows—100 kilos. of horn scraps, hair, &c., are treated for ten days at the ordinary temperature with 200 kilos. of 15% hydrochloric acid. The acid is drawn off and the residue, after washing with water, treated with 100 kilos. of 6% sodium hydroxide solution. At the end of 24 hours, an aqueous solution of 2 kilos. of potassium permanganate is added and the mixture allowed to stand for a further 12 hours. The residue is then washed and subjected to a pressure of 400 atmospheres. An alternative method is to pass carbon dioxide into the alkali solution, decant, and evaporate the solution. The product is finally clarified by means of hydrogen peroxide or permanganate, and may be used in place of casein for a variety of purposes. A patent, embodying a very similar process, is U.S.P. 926,999, 1909.[28]

Keratin substances are converted into digestible albumoses and peptoses containing sulphur by treatment with dilute mineral salts at moderate temperatures. The reaction is complete and the albumoses and peptoses are isolated, when a diluted sample, after treatment with phosphotungstic acid, or other reagent for albumoses, gives a filtrate containing but little amino acid.

Thermoplastic keratin compounds have been obtained by mixing intimately keratin with β-naphthol and subjecting the mixture to heat and pressure (U.S.P. 922,692, 1909[29]).

GENERAL PROPERTIES OF "KERATINS" (KERATOIDS)

Heated in the dry state, keratoids swell up, char, and evolve a characteristic odour of burnt feathers. Most of the keratoids are hygroscopic, taking up a large proportion of water without affording any indication of its presence* beyond the increase in weight of the substance. No systematic work appears to have been done with respect to the amount of water taken up by keratoids in atmospheres of varying humidity, except in the case of wool and gelatine. It would appear desirable to know, for instance, what is the regain of hair, horn, scales, &c., at various degrees of humidity, and to compare these regains one with another, and in particular with the definitely known regains of wool. The writer would suggest a phase rule study of the problem, on the lines of the work due to Cumming[30] on the hydrates of sodium carbonate, with a view to settling the point whether the taking up of moisture is merely a physical process, *i.e.* due to sorption,

*When subjected to mechanical tests, *e.g.* stress strain detns., the presence of moisture is found to alter the stress strain curve.

or has some chemical basis, or, further, the process may be compounded of the two.

The *keratoids* are quite insoluble in alcohol and ether, and are not much affected by boiling with water at the ordinary pressure; but when heated under pressure for a considerable time to 150°–200° C. they dissolve (*cf.* Bauer *supra*), with evolution of hydrogen sulphide to a turbid solution which does not gelatinise* on cooling, and gives on evaporation a residue insoluble in water.

Treated with alkalis, keratin substances swell up and are entirely dissolved by boiling alkaline solutions. Ammonia acts similarly but less strongly. On the addition of excess of acid to the solution of keratin in an alkali, a white flocculent precipitate is formed and hydrogen sulphide is evolved. In the case of wool, caustic soda solutions of 5–60° Tw. rapidly disintegrate wool, and when wet the wool can be drawn out to nearly twice its length, and on drying is very felted. Sodium hydroxide of 70° to 100° Tw. causes no felting and maximum tensile strength is observed at 82° Tw. (Washburn,[33] Matthews[34]).

Merrill,[32a] working on the action of sulphide on purified skin or hair, has arrived at the following conclusion—

(1) There is a reaction between keratin and the SH ion.

(2) This reaction so alters the structure of the protein that the residues are more readily attacked by the hydroxyl ion (*i.e.* by alkalis).

Bergmann and Stather,[32b] in a recent paper, have studied the action of sulphides on wool. Wool (250g.) was treated with a solution of sodium sulphide, acidified with hydrochloric acid, the water and the hydrogen sulphide being then removed under reduced pressure. The dry product was refluxed with concentrated hydrochloric acid, solution filtered, decolourised with animal charcoal, and neutralised with alkali. The precipitate contained 6·42% sulphur, corresponding to 9·7 grams of cystine. Wool not subjected to sodium sulphide treatment gave a precipitate containing 7·56% sulphur, corresponding to 13 grams of cystine. Decomposition of the cystine was much greater in the case of horse hair which had undergone the sodium sulphide treatment.

Treated with cold glacial acetic acid, horny substances swell up, and on boiling are largely dissolved. Whalebone is converted into a gelatinous substance by boiling with concentrated acetic acid, but tortoise shell is little changed by such treatment.

---

*In this connection the work of Gardner[31] is of interest, since it is not in entire agreement with the above, which is usually found in the literature. Gardner extracted 50 grams of wool with 1,500 cc. of water, and obtained ·825 gram solid residue, horn-like substance, *soluble in water* (*cf.* above), but insoluble in alcohol and containing a mere trace of mineral ash. The substance *was distinctly alkaline*, possessed feeble reducing properties, and decolourised an acid solution of potassium permanganate. The substance, called by Gardner "Wool Gelatine," has some function in mordanting with bichromate. It increases the amount of chrome fixed and retards the reduction of the mordant observed in old chrome baths.

Herz,[32] using 644 grams of wool (scoured in soap and soda, washed, acidified, extracted with ether, neutralised with ammonia, and washed), boiled with 16 litres of water for one hour (in two lots of eight litres), and on evaporation obtained ·71% of wool gelatine. From a second extraction he obtained ·4% wool gelatine. The properties are compared with those of a 1% gelatine solution, and the two are distinguished by applying the basic lead acetate test. There is a precipitate with wool gelatine, none with ordinary gelatine.

He further shows that wool gelatine is a mixture of three substances and states it is *acid towards litmus* (*cf.* Gardner *supra*).

On treatment with cold concentrated sulphuric acid, the keratoids swell up, and on heating dissolve more or less completely. The solution appears to contain syntonin, for on dilution with water and addition of potassium ferrocyanide it yields a flocculent precipitate and also gives a white flocculent precipitate when exactly neutralised.

When keratin is treated with chlorine water or bromine water, the substance undergoes no change in external appearance (this may be true of horn, &c., but is certainly not true of wool, *e.g.* work of B.R.A., Trotman, &c.), but after drying it is harsh to the touch and then dissolves in ammonia with evolution of nitrogen.

If chlorination* be excessive (work already done and in progress), a considerable portion, up to 30%, of wool substance in the case of wool keratin is destroyed.

Treated with fuming hydrochloric acid, most keratins swell up to a jelly and subsequently dissolve, though hair is unaffected by such treatment.

Other reactions and properties of keratin have been given in detail under the headings "Reactions of Keratin," "Hydrolysis Products," above.

Wool-keratin is of especial interest, and as a further illustration of the variability of the amounts of the elements present in a keratin, *i.e.* not taking account of the possible variation in configuration, the following data due to Bowman[35] are given—

	C	H	N	O	S	Loss†
Lincoln Wool	52·0	6·9	18·1	20·3	2·5	0·2
Irish Wool	49·8	7·2	19·1	19·9	3·0	1·0
Northumberland Wool ...	50·8	7·2	18·5	21·2	2·3	—
Southdown Wool	51·3	6·9	17·8	20·2	3·8	—
Mean	50·27	7·05	18·37	20·40	2·90	—

The mean of Bowman's analyses of wool-keratin correspond to the empirical formula $C_{43}H_{71}O_{13}H_{13}S$. It is of interest to note that in a paper on the sorption of hydrochloric and sulphuric acids by wool, Mills and Takamine[36] speak of wool-keratin as a substance of definite composition having the empirical formula $C_{42}H_{157}O_{15}N_5S$. This formula is based on analyses taken from Gmelin's "Handbook of Chemistry," but Whitely[37] has pointed out that owing to a misprint the percentages of nitrogen and hydrogen were transposed. The corrected average composition of keratin, according to analyses in question becomes C=49·96%, H=7·11%, N=16·65%, S=3·39%, and O (by diff.)=22·89%. The figures correspond to a formula $C_{41}H_{71}O_{14}N_{12}S$.

The only criticism which is necessary is that even with the finest apparatus available at the present day for ultimate analysis, no one could say with any degree of certainty whether the formula of keratin was, say, $C_{41}H_{70}O_{14}N_{12}S$, or $C_{41}H_{72}O_{14}N_{12}S$, assuming for the sake of argument that we could determine absolutely all the elements except oxygen.

It is of interest to note that lanuginic acid (first isolated by Champion[38] and further studied by Knecht and Appleyard,[39] obtained by Knecht on

*N.B.—The effect of chlorination is at present being investigated in greater detail.

†The loss in the first two analyses represents the mineral matter. In the last two this is included in the carbon.

treating wool with baryta under pressure at 170° C., has the following composition—C=41·61, H=7·31, N=16·26, S=3·35, O=31·44%, and that horn and human epidermis give very similar products when heated with water under pressure at 200° C.

With regard to the sulphur in wool-keratin, the work of Chevreul is of interest. Chevreul found that by treating wool with alkalis, the greater part of the sulphur is removed, but he was unable to extract the whole of it in this manner. Steeping wool 28 times in lime-water for 24 hours each time and washing with hydrochloric acid between each treatment, he reduced the sulphur content to ·46%. This wool was not blackened by boiling with lead acetate and excess of alkali hydroxide. (*See* reference 23a.)

Knecht (*supra*) found that lanuginic acid also gives a negative reaction with the alkaline lead reagent, from which fact he considers it probable that the *residual sulphur* of wool exists as lanuginic acid, or as some substance which readily yields lanuginic acid as a first product of its decomposition by reagents.

According to Prud'homme,[40] the sulphur in the wool is probably combined either as—

$$\mathrm{N{-}\overset{S}{\overbrace{C_n\,H_{2n}\,CO}}} \qquad \text{or} \qquad \mathrm{\overline{N{-}C_n\,H_{2n}\,CS}}$$

and is also contained in the natural colouring matter of the wool.

S. R. Trotman, E. R. Trotman, and R. W. Sutton[40a] have determined the sulphur content of various wools and find that results agree closely, the mean value being 3·22% of sulphur, and within the limits of the experiments described in the above preliminary notice, the authors believe that the amount of sulphur in wool is constant.

The behaviour of wool with coal-tar colouring matters suggests that wool-keratin has the constitution of an amino acid, in which case it should be possible to obtain the corresponding *diazo-compound*. The subject has been studied by Richard,[41] who apparently obtained some product resembling the diazonium derivatives, but Knecht[39] considers the theory to be untenable.

Fort and Lloyd[42] have attempted to condense the "assumed" amino group* in wool keratin with β-naphtho-quinone-4-sulphonic acid (potassium salt). This compound condenses with a number of amines giving coloured condensation products. With wool a brown compound (?) is formed, which changes in colour when treated with acid or alkali. They further show that alkali treatment increases the reactivity of the condensation, and they assume that alkali treatment develops the amino grouping.

The hydrolysis of wool by acids or alkalis is assumed to develop free amino groups according to the equation—

$$\mathrm{\overset{W}{\overbrace{NH{-}CO}}} + H_2O \rightleftharpoons \mathrm{\overset{W}{\overbrace{NH_2{-}COOH}}}$$

On the whole one is compelled to arrive at the conclusion that little real evidence as to the presence of the amino group in wool is to be obtained from the action of substances capable of forming condensation products.

*In this connection and for a review of the whole problem of the action of dyestuffs on wool samples treated in various ways, *e.g.* with alkalis, nitrous acid, quinone, &c., see E. R. Trotman.[43]

14—THE CHEMICAL ANALYSIS OF COTTON

xi.—THE ABSORPTION OF METHYLENE BLUE FROM BUFFERED SOLUTIONS

By Douglas Arthur Clibbens, Ph.D., and Arthur Geake, Ph.D.
(The British Cotton Industry Research Association)

I.—INTRODUCTION AND SUMMARY

In a previous communication[1] methods were described for the estimation of the absorption of Methylene Blue by cotton and the value of the measurement for the examination of bleached material was illustrated. It was shown among other things that accurate measurement necessitated great care in the preliminary washing of the cotton, since traces of acid or alkali which might occur in technically bleached material greatly influenced the observed value of the absorption, and a similar disturbance is caused by traces of alkali dissolved from the surface of storage bottles or other glass apparatus used in the determination. This effect, which is due to changes of hydrogen ion concentration, has been more closely examined in the work here described and a slightly modified method of measurement is given on page T130, rendering unnecessary the careful and time-consuming operation of washing which formed the chief disadvantage of the earlier method for routine purposes.

The new method prescribes the use of a solution of pure Methylene Blue hydrochloride, not in water, but in a dilute aqueous phosphate solution whose buffer action stabilises the hydrogen ion concentration and neutralises the effect of traces of acid or alkali which may be introduced with the cotton or from other sources. The phosphate buffer has been chosen to maintain the Methylene Blue solution at the neutral point (pH 7), whilst aqueous solutions of pure Methylene Blue hydrochloride are slightly acid. It is shown here and in other places that the absorption of Methylene Blue by cotton decreases with increasing acidity of the solution, and it is therefore to be expected that the values obtained from the neutral buffered solution will be higher than previous values recorded for unbuffered aqueous solutions. This is found to be the case and it is shown that the difference is mainly due to the changed hydrogen ion concentration, since the phosphate ion itself exerts little influence upon the absorption under the conditions of the measurement. The specific effect of the anion is much more marked with some other buffer salts than with phosphates, and it is far from true that two Methylene Blue solutions buffered at the same hydrogen ion concentration with different buffer mixtures necessarily yield identical absorption values with the same cotton. This fact does not, however, impair the value of the buffered solution in absorption measurements, since the same standard buffer being always used, the specific effect of the anion can be neglected. The great advantage of the new method is well illustrated by the table on page T132, and it is now being used in this laboratory for all measurements on normal and modified cotton cellulose.

During the course of many routine determinations, difficulty has sometimes arisen owing to the fact that different trade samples of "pure" Methylene Blue hydrochloride yielded different absorption values on the same cotton,

even when the dye content of the sample was determined by analysis and due quantitative allowance made for the impurities present. For such alleged pure samples a content of Methylene Blue hydrochloride has been found varying between 91% and 97%, calculated on the weight of dry material, and in some cases the impurities present exerted a qualitative or specific effect upon the absorption. Although this difficulty is to some extent avoided by the use of the buffered solution, it is recommended that Methylene Blue hydrochloride should always be purified by recrystallisation from water for the purposes of this measurement. By the use of such material in solution buffered with phosphates at pH 7, as here described, little difficulty has been encountered in obtaining standard reproducible absorption measurements.

Much of the work recorded in the previous communication has been repeated and amplified with the buffered solution, but no important modification of the earlier conclusions has been found necessary. In particular, the observation that mercerisation of cotton has little effect upon its Methylene Blue absorption is confirmed, and the point is emphasised since increased affinity for Methylene Blue is sometimes ascribed to increased colloidal dispersion of the cellulose, a view which is at present without experimental foundation.

The investigation has been extended to include oxy- and hydro-celluloses by a study of the effect of variations in the hydrogen ion concentration of the Methylene Blue solution upon the absorption of these modified celluloses. It is shown that the enhanced absorption characteristic of certain oxycelluloses suffers a rapid decrease with increasing acidity of the Methylene Blue solution, the behaviour being similar in this respect to that of normal cotton cellulose. Some hydrocelluloses, such for example as those formed by drying low concentrations of sulphuric acid into cotton at elevated temperatures, are also characterised by increased affinity for the basic dye, but with these the absorption is approximately the same from acid as from neutral solution. It is therefore possible to distinguish between enhanced absorption due to oxidising attack and that due to acid attack, and for this purpose two Methylene Blue solutions are used—the standard solution referred to above, buffered with phosphates at the neutral point (pH 7), and an acid solution of equal concentration in dyestuff prepared by dissolving Methylene Blue hydrochloride in $N/5$ acetic acid (pH 2·7). The two absorption measurements, from neutral and from acid solution, can be carried out on identically the same specimen by washing it free from Methylene Blue after the first measurement, and any uncertainty which may arise owing to non-uniform or local modification of the material to be tested is largely eliminated in this way. The test is described in detail on page T130.

Section II. of this paper describes the materials and methods of measurement used in this work; Section III. contains absorption measurements on cottons of several different growths scoured by a number of different boiling treatments; Section IV. discusses the effect of hydrogen ion concentration upon the absorption of bleached cotton; Section V. its effect upon the absorption of modified celluloses; and Section VI. records some measurements made on mercerised cotton. Finally, in Section VII., a comparison is made between the effect of ash alkali upon the absorption of Methylene Blue by cotton and its effect upon the absorption of the two triphenylmethane dyes, Methyl Green and Malachite Green.

II.—MATERIALS AND METHODS OF MEASUREMENT

Reagents

Methylene Blue Hydrochloride—Commercial "pure" Methylene Blue hydrochloride in the form of well-defined crystals was recrystallised two or three times from twelve times its weight of water. The moisture content of the air-dry crystals was estimated by drying a small portion at 110° C., and the dye content, which was in all cases between 99% and 100% of the theoretical, by titration with titanous chloride, the values so obtained being used for the preparation of the standard solutions described later.

The dye content of various "pure" commercial specimens of the hydrochloride varied between 91% and 97% of the theoretical, exclusive of moisture. In carrying out absorption measurements from aqueous unbuffered solutions, using these commercial "pure" samples, it was sometimes found that the 3% to 9% of impurity present exerted a specific effect upon the absorption for which due allowance could not be made except by carrying out absorption measurements upon a standard bleached cloth; thus, in a previous communication[1] the average value 0·45 was obtained for the absorption of well-scoured American yarns and cloths at an end concentration of 0·2 millimole per litre, but considerably lower values have been obtained since then for the same materials, using more carefully purified Methylene Blue hydrochloride. This difficulty, which has been encountered in other work,[2] and which affects the absolute value of the absorption rather than its relative significance in a series of measurements, is largely overcome by the use of the buffered solution described below, but it is recommended that recourse should always be had to a dyestuff preparation of 99% to 100% purity, such as can readily be obtained by the recrystallisation of commercial specimens.

In the preliminary investigation, the purity of the dye was controlled, not only by analysis, but also by measurements of electrical conductivity. The first recrystallisation of the commercial sample was always accompanied by an apparent fall of specific conductivity, but after two recrystallisations the value 102·2 $ohms^{-1}$ was obtained at 25° C., and a molecular dilution of 200 litres, and further crystallisation was without effect; this value agrees well with that given by Pelet-Jolivet[5] for the pure substance.

Neutral Buffered Methylene Blue Solution—The neutral (*p*H 7) buffered solution used in most of the measurements recorded later was *M*/250 in Methylene Blue, and had the following composition—

Potassium dihydrogen phosphate, KH_2PO_4	6·81 grams.
Normal sodium hydroxide solution, *N*.NaOH ...	29·63 ccs.
Pure Methylene Blue hydrochloride, $C_{16}H_{18}N_3SCl$ ...	1·279 grams.
Water	to 1 litre.

It is intended to use this solution in all future routine measurements of the absorption of normal or modified cotton cellulose.

Acid Methylene Blue Solution—It will be shown that in the examination of certain modified celluloses valuable information can be obtained by means of absorption measurements carried out not only in the neutral buffered but also in an acid Methylene Blue solution. For the latter purpose the following, also *M*/250 in Methylene Blue, was used (*p*H 2·7)—

Pure Methylene Blue hydrochloride	1·279 grams.
N/5 Acetic acid solution	to 1 litre.

Naphthol Yellow S Solution—This was employed for titration of the Methylene Blue solutions and contained approximately 0·6 gram of the

purified salt per litre. Naphthol Yellow S for the preparation of this solution consisted of a commercial "pure" sample of the sodium salt recrystallised from alcohol and water, and dried at 70° C. in vacuo, and the solution was standardised by titration against the neutral buffered Methylene Blue solution or against the acid solution when this was being used. An account of the titration method has already been given.[1] The presence of phosphate or of acetic acid in the solution did not affect the accuracy with which the end point could be observed, and the titrations did not differ by more than 1% from those obtained with pure aqueous solutions of Methylene Blue hydrochloride of equal concentration.

Method of Absorption Measurement

Measurements recorded in this paper were made by the titrimetric method substantially as described in the earlier communication, and it is intended to adopt this procedure in all future routine determinations—

A sample of the air-dry cotton weighing $2{\cdot}50 \pm 0{\cdot}01$ grams was added to 15ccs. of the neutral buffered Methylene Blue solution in a tube of the form previously described, care being taken to ensure thorough wetting. After standing overnight the solution was separated by centrifuging, and 10 ccs. titrated against the Naphthol Yellow S solution. The absorption in millimoles per 100 grams of dry cotton was calculated from the difference in titre of the 10 ccs. before and after immersion of the cotton, and with solutions of the above strength it is numerically equal to about one-fifth of the titre change; it is convenient in routine measurements to adjust the Naphthol Yellow S solution in order to render this relationship exact. Complete exhaustion of Methylene Blue from the solution under these conditions corresponds to an absorption of 2·4, and when measurements are being made on series of oxycelluloses which may be expected to attain very high absorptions, it is advisable to modify the method by taking 1 gram of material for analysis instead of 2·5 grams. Variations in the end concentration of the Methylene Blue solution have a greater effect upon the absorption from buffered than from the previously employed unbuffered solutions, and direct comparisons between measurements carried out with 1 gram and those with 2·5 grams of material cannot therefore be made. Recorded absorption values all refer to "dry" cotton and were calculated on the assumption that the air-dry material contained 6% of hygroscopic moisture, except in the case of measurements made on mercerised cotton when moisture determinations were carried out on separate samples; this assumption is sufficiently accurate for the purpose of the present analytical method. Although the absorption of Methylene Blue from buffered solutions by fully bleached cotton, which has been soured and washed as in normal technical practice, is not generally altered by further acidification of the material (*cf.* Table I.), it is considered advisable to preface the absorption measurement by short acid and water washing, and this has been done in all the experiments described in this paper except where the contrary is stated.

The procedure when the acid Methylene Blue solution is used is identical with that given above for the neutral buffered solution, the Naphthol Yellow S being standardised against the appropriate solution, but it is sometimes desirable to make both measurements on the same specimen, and this can easily be done by stripping the Methylene Blue from the sample after the first measurement. The excess of dye solution is first washed away with water and the sample then treated with successive fresh quantities of $N/5$ acetic acid at the boil until only a slight blue tinge is perceptible in the

material. This treatment is without effect upon the absorption of normal or modified cotton, and the sample can then be washed with water, air-dried, and the second absorption measurement made; it is immaterial in what order the two determinations are carried out.

In much of the work described later, absorption measurements have been made from the buffered solution by both the methods given in the earlier communication,[1] namely, the colorimetric, using $M/2500$ Methylene Blue solutions, and the titrimetric method, using $M/250$ solutions as outlined above, but since similar conclusions were reached by both methods, values given by the latter have alone been recorded. The titrimetric method is preferred partly because the addition of buffer salts to Methylene Blue solutions affects their colorimetric comparison, but also because variations in the end concentration of the Methylene Blue solution are of analytical importance in the colorimetric method owing to the lack of proportionality between the concentration of Methylene Blue and the colour intensity of the solution. In the titrimetric method, when a constant weight of cotton and a constant volume of dye solution of standard initial concentration are used, as described above, the effect of variations in end concentration upon the absorption value is of no analytical importance.

Measurement of the Hydrogen Ion Concentration of Methylene Blue Solutions

In a few cases it has been necessary to check the hydrogen ion concentration of Methylene Blue solutions used for absorption determinations, and for this purpose a quinhydrone electrode was employed which had previously been tested with $M/20$ potassium hydrogen phthalate[3] and compared with a hydrogen electrode in a range of buffer solutions. The two electrodes agreed well in solutions of *p*H less than 9, but at this value the quinhydrone electrode gave a somewhat low result, whilst at *p*H 10·2 a constant E.M.F. was not obtained—behaviour to be expected with this electrode—

Nominal *p*H of Buffer Solution ...		3·97	4·6	7·0	8·0	9·0	10·2
*p*H found	Hydrogen Electrode ...	3·97	4·62	7·00	8·02	8·97	—
	Quinhydrone Electrode	3·97	4·58	6·97	8·02	8·88	9·8–10·3

Although measurements of the hydrogen ion concentration of Methylene Blue solutions made with a hydrogen electrode have been recorded by Rona and Michaelis,[6] the present authors were not successful in attempts to carry out this measurement with a hydrogen electrode of the ordinary stationary type, using a continuous passage of hydrogen, and it was for this reason that recourse was had to the quinhydrone electrode. In $M/100$ Methylene Blue solutions, no stable E.M.F. was obtained with the hydrogen electrode, whilst in $M/500$ or $M/2500$ solutions, although reasonably constant E.M.F.'s were recorded, the corresponding hydrogen ion concentrations were considerably higher than those found with the quinhydrone electrode. Buffered solutions of Methylene Blue showed the same E.M.F. towards the quinhydrone electrode as did the buffer solutions in the absence of Methylene Blue, but with the hydrogen electrode the calculated *p*H was lower in the presence of the dye than in its absence—

Methylene Blue Solution	*p*H found: Hydrogen Electrode	*p*H found: Quinhydrone Electrode
$M/100$ in water	Negative; unstable E.M.F. ...	4·06
$M/500$,, ...	3·57 ...	4·80
$M/2500$,, ...	4·36 ...	5·14
$M/2500$ buffered at *p*H 4·6 ...	4·15–4·30 ...	4·60
*p*H 4·6 buffer solution *alone*	4·62 ...	4·58

The failure of the hydrogen electrode in the presence of Methylene Blue is doubtlessly due to reduction of the dye, since when an electrode which has been used in contact with Methylene Blue is washed with water until the washings are colourless, immersion in an oxidising solution immediately produces a blue colour.

Methyl Green IY and Malachite Green

For comparison with the results obtained by the use of Methylene Blue, a few measurements were made with two triphenylmethane dyes, namely, Methyl Green, as zinc double chloride, and Malachite Green, as oxalate. The purest available commercial products were used, the Methyl Green being assumed to have the composition $C_{26}H_{33}N_3Cl_2+ZnCl_2$ after drying at 110° C., and the Malachite Green the composition $C_{23}H_{25}N_2+1{\cdot}5\ C_2H_2O_4$ after drying at the ordinary temperature over phosphorus pentoxide; absorptions are expressed in millimoles per litre on the assumption of these formulæ.

Cotton samples weighing 2·5 grams were steeped overnight at the ordinary temperature in 50 cc. of $M/1000$ Methyl Green or $M/5000$ Malachite Green, and the change in concentration of the dye solution determined by colorimetric methods.

Neither dye could be estimated by titration with Naphthol Yellow S, and the concentrations chosen for absorption measurement were those found most convenient for colorimetric comparison. The colour intensity of Methyl Green solutions is proportional to the concentration of the dye over a wide range examined, namely, $M/100$ to $M/2500$, but greater difficulty was experienced in the colorimetric comparison of Malachite Green solutions. The shade of solutions of this dye changes with changing concentration, but over the range of low concentrations $M/1000$ to $M/10000$ the disturbance caused by this shade variation is not great and proportionality can be assumed between colour intensity and dye concentration.

III.—ABSORPTION OF METHYLENE BLUE BY BLEACHED COTTON FROM NEUTRAL BUFFERED SOLUTION

Advantages of the Method

In order to show the advantages of the use of a buffered solution compared with that of the ordinary aqueous solution employed in earlier work, a number of measurements were made in which the precautions previously considered necessary were omitted or modified. The errors caused by these omissions are shown in Table I. for both buffered and unbuffered Methylene Blue solutions—

Table I.

Conditions Altered	Cotton Sample No.	% Error in Absorption Measurement: Unbuffered Solution	% Error in Absorption Measurement: Buffered Solution
1 cc. 0·1N NaOH added to 1 litre Methylene Blue	69	+26	−3
1 cc. 0·1N HCl added to 1 litre Methylene Blue	69	−13	±0
Kier boiled and washed with water but not soured	142EK1	+55	+3
	134EK2	+79	+8
	132EK3	+71	+7
Technical full bleach without further laboratory washing ...	69	+35	−2
	67	+37	+3
	182	+51	−1
New Glassware	69	+26	±0
Rapid Acid Wash	132EK3	−20	+5

The table shows that the addition of only 1 cc. of decinormal acid or alkali to a litre of the Methylene Blue solution caused large errors in the absorption from unbuffered solution, but was without significant effect when the buffered solution was used. The plus sign in the table indicates that the absorption was greater than that measured by the normal procedure, the minus sign that it was less; thus, in unbuffered solution, the effect of the slight addition of alkali was greatly to increase the absorption and of added acid to diminish it. When measurements were made on scoured cotton washed off with water after the kier boil, but otherwise untreated, large errors occurred with the unbuffered solution in the direction which would be predicted on the assumption that the cotton still contained free alkali; the errors in the use of the buffered solution were again much smaller. Values are also recorded for materials which had received a technical full bleach with no laboratory washing previous to the measurement. Very considerable errors again resulted with the use of unbuffered solutions, and these were also in the direction which indicates presence of excess alkali on the cotton, or in the solution, although the last operations in the technical treatment of all these samples were souring and washing; it must be assumed either that the technical sour was not very efficient or that the water used for washing was sufficiently alkaline to produce this effect. Alkali dissolved from the surface of new glassware used in the analytical operations also causes a large error which is corrected by the use of a buffered solution. Finally, an example is given of measurements made on a bleached yarn which was washed in the laboratory with dilute acid and distilled water previous to absorption measurement, the washing being, however, less carefully carried out than usual. The "rapid acid wash" referred to in the table consisted in steeping the cotton for an hour in decinormal sulphuric acid, washing twelve times with distilled water, and centrifuging the material between each wash, steeping in water for about three hours, re-washing and drying at room temperature. This operation, which for most purposes would be considered very thorough washing, has yet left sufficient acid in the material seriously to affect the absorption from unbuffered solution. For the complete removal of acid from cotton by water washing, it has frequently been observed that lengthy steeping is of much greater importance than frequent changes of wash water. When the buffered solution is employed, this "rapid acid wash," which can be completed within one working day, may be used with safety.

Influence of Origin of Cotton

It was shown previously with unbuffered solutions that the absorption of cotton scoured by a standard process varies with the origin of the material, different growths yielding different values after identical bleaching treatment, and this is still found to be the case when the neutral buffered solution is used. The absorptions of a number of cottons boiled with 1% sodium hydroxide solution for six hours at 20 lbs. excess pressure are collected in Table II. The values given by Texas cottons are sharply differentiated from those of the Egyptian growths, although the relative difference is not so great as when an unbuffered solution was used, and no significant difference is observed between different Egyptian varieties; for normally well-scoured American cotton, the absorption by the new method falls between 0·8 and 0·9, and for well-scoured Egyptian cotton between 1·0 and 1·1. The table contains measurements made on a number of authentic samples of cottons of known strain grown in India, and it will be seen that native Indian types

(Surat, Sircar, &c.) yield consistently higher values than the strains of American origin (Punjaub American, Cambodia, &c.); in general, however, the cottons grown in India are very variable, a characteristic feature of the chemical properties of this group.

Table II.

Influence of Conditions of Boiling

By means of unbuffered Methylene Blue solutions, it was shown that, after a normal bleach, cotton absorbs very much less Methylene Blue than in the grey state, and that this change takes place during alkali boiling, the absorption of the bleached material varying with the conditions of the kier boil. This conclusion has been confirmed and amplified by the use of the neutral buffered solution for absorption measurements. In general, and within the limits here employed, the more severe the alkali treatment with respect to duration, temperature (pressure) of boil, and alkali concentration, the lower is the absorption. An open boil results in a considerably higher absorption than does a pressure boil under otherwise identical conditions, as shown in Table III. for a number of different varieties of cotton.

Table III.

Duration of boil, 6 hours. Concentration of Sodium Hydroxide, 1%.

Cotton* Sample No. and Variety.		Absorption, M. Mols./100 gms. After Open Boil.	After Boil at 20 lbs. pressure
133	Uppers, Egyptian	1·45	0·98
132	Sakel, Egyptian	1·51	0·98
150	Tanguis, Peruvian	1·51	1·15
153	Mitafifi, Peruvian	1·42	0·87
151	Pima, American from Egyptian seed ...	1·73	1·14
152	Long-staple Brazilian	1·27	0·85

*These samples had all been chemicked after the kier bo l, an operation which affects the absorption, however, at most to but a slight extent.

The effect of pressure is most pronounced in passing from an open boil to a boil under slight excess pressure (10 lbs.), further increase to 40 lbs. having a relatively smaller effect, as shown in Table IV. by three series of experiments on American, Egyptian, and Indian cottons. The large fall in absorption between the open and the 10 lbs. pressure boil may be due to a better penetration of the material by the alkali rather than to purely chemical causes.

Table IV.

Duration of boil, 6 hours. Concentration of Sodium Hydroxide, 1%.

Kier Boil No. and Pressure		Absorption, M. Mols./100 gms. American Yarn No. 149		Egyptian Yarn No. 148		Indian (Broach) Yarn No. 141
EK11 open ...	...	1·10	...	1·40	...	1·69
EK7 10 lbs.	...	0·95	...	1·22	...	1·47
EK6 20 lbs.	...	0·86	...	1·11	...	1·47
EK8 30 lbs.	...	0·82	...	1·04	...	1·42
EK10 40 lbs.	...	0·83	...	0·99	...	1·39

Increase in the concentration of the alkali from 0·5% to 3% at constant pressure and duration of boiling also produces a slight gradual decrease of absorption.

Table V.

Duration of boil, 6 hours. Pressure of boil, 20 lbs.

Kier Boil No. and Concentration of NaOH		Absorption, M. Mols./100 gms. American Yarn No. 149		Egyptian Yarn No. 148		Indian (Broach) Yarn No. 141
EK23 0·5% ...	...	0·89	...	1·23	...	1·61

EK15 2% ...	...	0·81	...	1·02	...	1·39
EK16 3% ...	...	0·80	...	0·90	...	1·26

Beyond a certain point, determined presumably by the penetration of the alkali through the bulk of the material, the duration of boiling under otherwise constant conditions is without great effect upon the absorption.

Table VI.

Pressure of boil, 20 lbs. Concentration of Sodium Hydroxide, 1%.

Kier Boil No. and duration of Boil		Absorption, M. Mols./100 gms. American Yarn No. 149		Egyptian Yarn No. 148		Indian (Broach) Yarn No. 141

EK6 6 ,, ...	...	0·86	...	1·11	...	1·47
EK24 2×6 ,, ...	...	0·81	...	0·97	...	1·32

The effect of employing more rigorous conditions of kier boiling with respect to time, temperature, or alkali concentration, is always more marked with the Egyptian and Indian cottons than with the American sample, and there is evidently a tendency for the absorption to become identical in the three varieties, though this limit is not reached under the conditions so far recorded. When, however, the concentration of sodium hydroxide is raised to 3% in a six-hours' kier boil at 40 lbs. pressure, the absorptions of the three varieties are found to approach one another still more closely.

		Absorption, M. Mols./100 gms. American Yarn No. 149		Egyptian Yarn No. 148		Indian (Broach) Yarn No. 141
EK26 ...	...	0·70	...	0·82	...	0·96

The form in which the cotton is boiled also appears to exert a slight effect upon the resulting absorption, due presumably to its effect upon the ease and efficiency of the penetration of the alkali. The American Yarn No. 149, for which results have already been given, was also available in the form of a woven fabric (No. 166), where it was employed as weft yarn, the warp being spun from the same cotton mixing, and a series of experiments were carried out with this fabric, the results of which are compared below with those of a similar series made with the yarn and already recorded.

Table VII.

Duration of boil, 6 hours. Concentration of Sodium Hydroxide, 1%.

Pressure of boil ...	0	10	20	30 lbs.
Absorption, M. Mols./100 gms.—				
Yarn No. 149	1·10	0·95	0·86	0·82
Cloth No. 166	1·12	1·08	0·98	0·94

The absorption is slightly higher when the cotton was boiled in cloth than when boiled in yarn form.

In the next table some results are collected for a series of samples taken from large batches of American sliver, boiled for 10 hours at 40 lbs. on a technical scale with sodium hydroxide of 2% initial concentration, conditions which are more severe than those generally employed in the bleaching of cotton textiles. The treatment was slightly varied from batch to batch as indicated in the table, several of the samples being the same as those examined in a previous communication. The results with the exception of the last are much lower than those obtained for American cottons under normal bleaching treatment (*cf.* the average 0·86 in Table II. for American yarns boiled with 1% sodium hydroxide at 20 lbs. for six hours), and they offer a further example of the way in which the absorption is lowered by increasing the severity of the alkali treatment, or by improved penetration of the alkali due to looser packing of the cotton or to both causes.

Table VIII.

Cotton Sample No.		Nature of Kier Liquor	Absorption, M. Mols./100 gms.
107R	2% NaOH	alone ...	0·71
110R	,,	preceded by benzene extraction	0·69
73R	,,	preceded by water boil	0·62
76R	,,	+ olein	0·68
97R	,,	+ soap	0·79

The last example in this table shows the increased absorption which results from the presence of soap in the kier liquor, an effect which was noted previously but which is accentuated by the use of the neutral buffered Methylene Blue solution for absorption measurement. Other examples have been observed in which very greatly enhanced absorptions have resulted from the use of soap in technical kier boils, the absorption being reduced to a normal value by washing with acid and extracting with chloroform, and the presence of soap being confirmed by the constants of the material thus extracted.

IV.—EFFECT OF HYDROGEN ION CONCENTRATION UPON THE ABSORPTION OF METHYLENE BLUE BY BLEACHED COTTON

From examples already given it will be evident that the hydrogen ion concentration of the Methylene Blue solution is a very important factor determining the absorption of the dye by bleached cotton. Attempts were made to examine quantitatively the effect of variations in hydrogen ion concentration by using a number of Methylene Blue solutions buffered over the range *p*H 10 to 3, but these attempts failed since the anions in the different buffer salts employed exerted different specific effects upon the absorption. This did not affect the use of a standard buffered solution for analytical purposes, but it did prevent an evaluation of the exact influence of hydrogen ion concentration changes. In order therefore to study this effect closely, measurements were made of the absorption of a bleached cloth (No. 69) from a pure aqueous solution of Methylene Blue hydrochloride and from solutions to which very small additions of sodium hydroxide or sulphuric acid had

been made. After absorption had taken place, determinations of the hydrogen ion concentration of the equilibrium solution were carried out with the quinhydrone electrode, and the results are recorded in Table IX. together with values obtained on the same cotton for the absorption from solutions buffered with phosphate mixtures (*p*H 6 to 8) and from the solution in 0·2*N* acetic acid (*p*H 2·7); in Fig. 1 the absorption is plotted against the *p*H value of the equilibrium solution.

Table IX.

Methylene Blue Solution used		*p*H of Solution after Absorption		Absorption M. Mols./100 gms.
M/250 Methylene Blue buffered with phosphates	250 cc. 0·2*M* KH_2PO_4 + 226 cc. *M*/5 NaOH	7·8	...	0·92
	,, + 206 cc. ,,	7·5	...	0·89
	,, + 148 cc. ,,	7·0	...	0·85
	,, + 76 cc. ,,	6·5	...	0·83
	,, + 28·5 cc. ,,	6·0	...	0·76
15 cc. *M*/250 Unbuffered Methylene Blue	+ 1·0 cc. *M*/100 NaOH	5·8	...	0·70
15 cc. ,, ,, ,,	+ 0·5 cc. *M*/100 NaOH + 0·5 cc. H_2O	5·0	...	0·58
15 cc. ,, ,, ,,	+ 1·0 cc. H_2O	4·2	...	0·49
15 cc. ,, ,, ,,	+ 0·5 cc. 0·01*N* H_2SO_4 + 0·5 cc. H_2O	3·8	...	0·43
M/250 Methylene Blue in 0·2*N* Acetic Acid	... ...	2·7	...	0·31

The curve shows that the relation between *p*H and absorption is approximately linear over this range, very small changes of hydrogen ion concentration having a significant influence upon the absorption. Values obtained from solutions in acetic acid and in the phosphate buffer mixtures also lie near this curve, but it must again be emphasised that this is not the case with many other buffer salts, the effect of the anion often completely obscuring the true hydrogen ion effect. The phosphate ion in this dilution is apparently without great effect upon the absorption from *M*/250 Methylene Blue hydrochloride solution, a conclusion which has been reached from other evidence. Thus when the *p*H 7 phosphate buffer solution in Table IX. was diluted tenfold, its *p*H value was only very slightly affected, and the absorption of Methylene Blue by the cotton from a solution made up in the diluted buffer was only slightly different from that given in the table for *p*H 7·0, although the total phosphate content of the solution had been reduced tenfold.

It will be noticed that the pure aqueous solution of Methylene Blue hydrochloride is acid and remains acid even after the additions of sodium hydroxide recorded in the table; this is due to the hydrolysis of the dye salt (*cf.* Rona and Michaelis[6]).

V.—EFFECT OF HYDROGEN ION CONCENTRATION UPON THE ABSORPTION OF METHYLENE BLUE BY OXY- AND HYDRO-CELLULOSES

It has been observed that the effect of variations in the hydrogen ion concentration of the Methylene Blue solution upon the absorption of oxycelluloses, whether these are characterised by enhanced absorption or not, is similar to the effect of the same variations in the case of normal bleached cotton. Many hydrocelluloses possess no higher absorptions than those of the bleached cotton from which they were formed, and these are generally influenced by changes of hydrogen ion concentration in a similar manner to that observed for normal and oxidised cotton cellulose. There exists,

however, a type of hydrocellulose, formed for example by drying low concentrations of sulphuric acid into cotton at elevated temperatures, which possesses much higher absorptions than those of bleached cotton, and such enhanced absorptions are influenced by changes of hydrogen ion concentration in a manner very different from that observed in any other case. The absorptions of some samples of modified celluloses have therefore been measured in a range of Methylene Blue solutions of different hydrogen ion concentrations, namely, in the phosphate buffered solution at *p*H 7, in a sodium acetate-acetic acid buffer at *p*H 4·6, in 0·2*N* acetic acid solution (*p*H 2·7), and in solutions 0·01*N* and 0·1*N* in free sulphuric acid (*p*H 2·1 and 1·2 respectively). The results for a bleached cloth, for an oxycellulose and two hydrocelluloses all prepared from it are given in Table X., whilst the absorptions of the four materials are plotted against the *p*H of the Methylene Blue solution in Fig. 2. It is not inferred that the change in absorption on passing from one Methylene Blue solution to another throughout this range is due entirely to hydrogen ion concentration changes, since the difference in quantity and quality of anions present in the various solutions certainly influences the results to some extent.

Table X.

Material	Absorption, M. Mols./100 gms.				
	Phosphate Buffer *p*H 7	Acetate Buffer *p*H 4·6	0·2*N* HAc. *p*H 2·7	0·01*N* H_2SO_4 *p*H 2·1	0·1*N* H_2SO_4 *p*H 1·2
Bleached Cloth No. 182	0·89	0·70	0·31	0·33	0·48

Hydrocellulose No. A19	1·46	1·36	1·91	1·92	1·37
,, No. A20	2·29	2·19	2·23	2·42	2·02

The oxycellulose O2, which was prepared by the action of alkaline hypobromite upon cloth No. 182,[2] possessed greatly enhanced absorption when compared with the cloth by the standard absorption method, using the buffered Methylene Blue solution at *p*H 7, and Fig. 2 show that its absorption was affected by changes in the Methylene Blue solution in a similar manner to that observed for the cloth itself. With the exception of the solution in decinormal sulphuric acid, a steady fall in absorption was recorded as the *p*H value of the solution decreased, and this fall was more rapid with the oxycellulose than with the bleached cloth, so that at *p*H 2·1 (0·01*N* sulphuric acid solution) the absorptions of the normal and modified celluloses had become practically identical.

The two hydrocelluloses, A19 and A20, which were prepared by drying 0·1*N* sulphuric acid into cloth No. 182 at different temperatures, also possessed enhanced absorptions, compared with the cloth itself in the neutral buffered solution, but the curves in Fig. 2 show that with increasing acidity of the Methylene Blue solution these absorptions tended to increase rather than to fall as in the previous cases (no particular significance is attached to the exact form of these curves for reasons already stated). The oxycellulose O2, and the hydrocellulose A19, had almost the same absorptions at *p*H 7, namely, 1·38 and 1·46 respectively, whilst at *p*H 2·7 the value for the oxycellulose had *fallen* to 0·66, that of the hydrocellulose having *risen* to 1·91.

In view of these results, a large number of oxycelluloses and hydrocelluloses have been examined, but for the present analytical purposes the examination has been confined to a comparison of the absorptions from Methylene Blue solutions at *p*H 7 (standard method) and at *p*H 2·7 (0·2*N* acetic acid). For bleached cotton and for oxycelluloses of different types

prepared in a variety of different ways, the ratio of the absorption at *p*H 7 to that at *p*H 2·7 was always greater than 2, and the same was true for hydrocelluloses resulting from that type of acid attack which shows no tendency to cause enhanced absorption. Three forms of acid attack have, however, been examined, which lead eventually to enhance absorption, namely, (1) dilute sulphuric acid dried into cotton at elevated temperatures; (2) dilute phosphoric acid similarly dried into cotton; and (3) the steeping of cotton in concentrated sulphuric acid at ordinary temperatures. When enhanced absorption results from any of these causes the ratio of the value obtained at *p*H 7 to that obtained at *p*H 2·7 is less than 2 and generally less than 1. Table XI. records, for example, the absorptions of hydrocelluloses formed by steeping cloth No. 182 at the ordinary temperature, and for a constant time in sulphuric acid of increasing concentrations.

Table XI.

Concentration of H_2SO_4	0	100	200	300	grams per litre.
Absorption at *p*H 7 ...	0·89	0·82	0·83	0·82	millimoles per 100 grams.
,, at *p*H 2·7 ...	0·31	0·28	0·26	0·25	,, ,,
Ratio *p*H 7/*p*H 2·7 ...	2·9	2·9	3·2	3·3	
Concentration of H_2SO_4	400	500	600	700	grams per litre.
Absorption at *p*H 7 ...	0·79	0·79	0·94	1·30	millimoles per 100 grams.
,, at *p*H 2·7 ...	0·27	0·36	0·72	1·76	,, ,,
Ratio *p*H 7/*p*H 2·7 ...	2·9	2·2	1·3	0·74	

It will be seen that with increasing acid concentration the absorption at *p*H 7 falls to a minimum (400–500 gms. H_2SO_4 per lit.), and then begins to rise steadily. At the minimum the ratio of the absorptions at *p*H 7 and *p*H 2·7 falls rapidly, and with acid at 700 gms. per lit. the hydrocellulose absorbs more Methylene Blue from the acid than from the neutral solution; the preparation formed by the action of sulphuric acid at 600 gms. per lit. has an absorption at *p*H 7 very little different from that of the untreated material, whilst in the measurement made at *p*H 2·7 the value of this hydrocellulose is more than twice that of the bleached cotton.

Table XII. shows similar values obtained by drying 0·025*N* sulphuric acid into the cloth for a constant time at increasing temperatures.

Table XII.

Temperature of drying	20°	50°	70°	90°	110°	C.
Absorption at *p*H 7 ...	0·89	0·65	0·59	0·66	0·67	m.mols. per 100 g.
,, at *p*H 2·7 ...	0·31	0·28	0·36	0·68	0·74	,, ,,
Ratio *p*H 7/*p*H 2·7 ...	2·9	2·3	1·6	0·97	0·91	

The values obtained at *p*H 7 within this temperature range never reach that of the unattacked material (0·89), the minimum attained in the initial fall being only just passed at 110° C., so that no enhanced absorption is actually observed, but for measurements made in Methylene Blue solutions of *p*H 2·7, the minimum is attained at 50° C., whilst at 90° C. very greatly enhanced absorptions are found.

Finally, Table XIII. shows the results of a similar series of experiments in which *M*/10 phosphoric acid was dried into the cloth at various temperatures. and the same rapid fall in the absorption ratio is again observed.

Table XIII.

Temperature of drying	20°	50°	70°	90°	110°	130°	C.
Absorption at *p*H 7 ...	0·89	0·83	0·93	1·39	1·64	1·82	m.mols./100 g.
,, at *p*H 2·7 ...	0·31	0·52	0·71	1·19	1·70	2·14	,,
Ratio *p*H 7/*p*H 2·7 ...	2·9	1·6	1·3	1·2	0·97	0·85	

Further details regarding the preparation and properties of these hydrocelluloses will be found in the succeeding communication—"Chemical Analysis of Cotton, Part XII.—Hydrocellulose"—and it is sufficient to say here that measurements of the absorption ratio at *p*H 7 and *p*H 2·7 enable a sharp distinction to be made between enhanced absorption due to the oxidising and that due to the acid attack of cotton.

In adapting the measurement of absorption ratio as a test for technically modified material, it may generally be advisable to carry out the two measurements on identically the same specimen to avoid erroneous conclusions due to non-uniformity of the material. This can be done without difficulty by stripping the Methylene Blue from the cotton after the first determination, as explained on page T130. That this procedure does not introduce serious error is shown by the following figures yielded by two specimens of the bleached cloth No. 182, to obtain which the absorption of the first specimen was measured at *p*H 7, the second at *p*H 2·7, both specimens being then stripped and the absorption of the first determined in solution at *p*H 2·7 and the second in *p*H 7 solution.

Specimen I.		Specimen II.	
Absorption at *p*H 7	0·84	Absorption at *p*H 2·7	0·33
Absorption at *p*H 2·7 after stripping	0·30	Absorption at *p*H 7 after stripping	0·82

The two measurements at *p*H 7 and the two at *p*H 2·7 are in substantial agreement.

VI.—THE ABSORPTION OF METHYLENE BLUE BY MERCERISED COTTON

It has previously been stated[1] that mercerisation has no marked effect upon the absorption of Methylene Blue by cotton, and this has now been confirmed by measurements in the range of Methylene Blue solutions used for the investigation of hydro- and oxy-celluloses. The absorption of cloth No. 182 after mercerisation without tension was slightly lower than that of the unmercerised cloth in each solution—

	Absorption, M. Mols./100 gms.				
Material	Phosphate Buffer *p*H 7	Acetate Buffer *p*H 4·6	*N*/5 HAc. *p*H 2·7	*N*/100 H_2SO_4 *p*H 2·1	N/10 H_2SO_4 *p*H 1·2
Cloth 182, unmercerised	0·89	0·70	0·31	0·33	0·48
,, mercerised ...	0·81	0·69	0·27	0·28	0·47

The following results were obtained from trade samples of an Egyptian cotton fabric which had been bleached by different methods and mercerised under tenson—

	Absorption, M. Mols./ 100 gms.	
Bleaching treatment	Mercerised.	Unmercerised.
Hot soaped, pressure boiled, chemicked	1·04 ...	1·13
,, open boiled, chemicked	1·39 ...	1·28
,, chemicked	1·81 ...	1·95

These figures lend no support to the statements of Harrison,[4] Schwalbe,[7] and others, that mercerised cotton is characterised by increased affinity for Methylene Blue.

VII.—THE ABSORPTION OF OTHER BASIC DYES BY COTTON

The work described in this and the earlier paper was carried out solely with the object of exploring the value of Methylene Blue absorption measurements as a means of analytical control in cotton technology. The only

definition attached to the word "absorption" is that derived directly from the method of measurement, which consists in determining the change in concentration of a dye solution when cotton is introduced into it, and one of the most noteworthy results is the discovery of the close correlation which undoubtedly exists between ash alkalinity and the Methylene Blue absorption of cotton; this extends to cottons containing cellulose modified by the action of oxidising agents.[2] A few measurements have been made to determine whether a similar correlation exists between ash alkalinity and the absorption of other basic dyes by cotton.

In Table XIV. there are given the ash alkalinities and the absorptions of Methylene Blue, Malachite Green, and Methyl Green by four different bleached cottons from aqueous (unbuffered) solutions of the dyes. The absorptions correspond to different end concentrations for the three dyes, the concentrations of Malachite Green and Methyl Green being such as could be conveniently determined by colorimetric methods (*cf.* p. T132). It is not therefore intended to make any comparison between the absorptions of the three different dyes by the same cotton, the object of the measurements being to determine for each dye the effect of washing the cotton with acid or of lowering its ash alkalinity. The four cottons in the table had been kier boiled in the form of unspun or loose material with sodium hydroxide soluton of 2% initial concentration at 40 lbs. excess pressure and were then well washed with water in the course of technical operations. They had not been soured and their ash alkalinities (in the column headed "untreated") were on the average higher than is usual in cotton fully bleached for textile purposes; after thorough acid washing (column headed "acid washed") the cottons possessed very low ash alkalinities.

Table XIV.

	Cotton No. 24R		Cotton No. 88R		Cotton No. 155R		Cotton No. 73R	
	Un-treated	Acid washed	Un-treated	Acid washed	Un-treated	Acid washed	Un-treated	Acid washed
Ash alkalinity, milli-equivs/100 g.	1·62	0·02	2·38	0·05	2·41	0·05	0·90	0·09
Absorption, Methyl Green millimols/100 g.	0·72	0·21	1·50	0·22	1·39	0·23	0·43	0·16
Absorption, Malachite Green millimols/100 g.	0·14	0·09	0·30	0·09	0·26	0·08	0·07	0·08
Absorption, Methylene Blue millimols/100 g.	0·75	0·40	0·80	0·41	0·66	0·36	0·49	0·34

The table shows that the absorptions of Methyl Green and Malachite Green were very greatly decreased by the reduction of ash alkalinity which accompanied acid washing, and the order of absorption of both dyes by the untreated cotton is almost identical with the order of ash alkalinity. The apparent large changes of absorption observed on acid washing are, however, not real, but are due to the fact that the cottons before washing contained sufficient soluble alkali to convert considerable proportions of the colour salts into colour bases, which remained partly in the solution and were partly absorbed by or precipitated on the cotton. This effect was readily detected since, the bases being colourless, the introduction of cotton into the dye solution resulted in greatly decreased colour intensity in the liquid without a corresponding increase in the "dyed" shade of the cotton, and

the colour could be partially restored in the solution by separating it from the cotton and warming with dilute acid. The absorption as measured colorimetrically by the change in concentration of the coloured substance includes the whole of the dye which is converted into colour base.

The absorption of Methylene Blue by these samples was also diminished by acid washing, but it is not possible to decide whether the apparent absorption by the untreated cotton is due in part to a precipitation of the corresponding base, since, the latter being as deeply coloured as the hydrochloride, its formation would not be observed.

In Table XV. measurements are given for a cloth which had been submitted to four different technical scouring processes of varying efficiency, each sample having been soured and washed as the last operation in its technical treatment. The ash alkalinities (in the column headed "untreated") were therefore lower on the average than those of the loose cottons in Table XIV., whose technical treatment did not include a sour, but in every sample thorough acid washing produced a further fall of ash alkalinity.

It will be seen that the effect of acid washing upon the absorptions of Methyl Green and Malachite Green was almost negligible, although that of Methylene Blue still suffered an important fall as a consequence of the diminished ash alkalinity. Thus a great difference in behaviour is shown between the samples of Table XV. and those of Table XIV., a difference which can only be due to qualitative differences of the ash alkali. In the series of samples described in Table XIV., the high ash alkalinity was almost certainly due to traces of sodium carbonate, residues of alkali left in the material after the kier boil, whilst in the second series the ash alkalinity was chiefly due to lime and magnesium salts derived from the chemic and from the hard water used during washing. When cotton contains traces of alkali in soluble form, the absorption of basic dyes is high, but the measurement is unreal at least in the case of triphenylmethane dyes owing to the ready formation of the colour bases. On the other hand, the presence of traces

Table XV.

	Continuous low pressure caustic scour, chemic, sour, and wash		Boiled with water at 30 lbs. excess pressure, sour, and wash		Scoured with caustic soda at 40 lbs. excess pressure, chemic, sour, and wash		As sample No. 89, then caustic scour at 30 lbs. excess pressure, chemic, sour, and wash	
	Un-treated	Acid washed	Un-treated	Acid washed	Un-treated	Acid washed	Un-treated	Acid washed
Ash alkalinity, milli-equivs/100 g.	0·84	0·27	1·03	0·28	1·43	0·27	0·60	0·30
Absorption, Methyl Green, millimols/100 g. ...	0·64	0·61	0·56	0·58	0·52	0·41	0·44	0·43
Absorption, Malachite Green, millimols/100 g. ...	0·20	0·22	0·22	0·20	0·16	0·16	0·14	0·14
Absorption, Methylene Blue, millimols/100 g. ...	1·02	0·90	0·95	0·72	0·96	0·60	0·55	0·45

of insoluble alkalis in cotton has little or no effect upon the absorption of triphenylmethane dyes, but causes an enhanced absorption of Methylene Blue.

The absorptions of all three dyes, determined after acid washing, place the samples of Table XV. in the same order, namely, the order of increasingly vigorous scouring treatment. The lower absorptions of cotton boiled in the loose state compared with that of cotton boiled in yarn and cloth form has already been commented upon (p. T136), and a comparison of Tables XIV. and XV. shows that this behaviour is characteristic of all three dyes.

15—THE CHEMICAL ANALYSIS OF COTTON
xii.—HYDROCELLULOSE

By Constance Birtwell, M.Sc., Douglas Arthur Clibbens, Ph.D., and Arthur Geake, Ph.D.

(The British Cotton Industry Research Association)

INTRODUCTION AND SUMMARY

Under certain conditions, the action of acids upon cotton cellulose produces changes in its physical and chemical properties, the most obvious of which are loss of tensile strength and ultimate disruption of the cotton hair. The name "hydrocellulose" was originally applied to the structureless powdery material obtained as the result of such acid action, but it is now recognised that complete loss of tensile strength does not correspond to any definite stage of chemical degradation, that the properties of powdery hydrocellulose are variable, and that attempts to prepare a chemically homogeneous substance which can be considered as a primary product of cellulose hydrolysis have so far been unsuccessful. It is a debatable theme whether the name "hydrocellulose" should be reserved for such a substance, at present hypothetical, but on grounds of practical convenience the word has been used in this paper to designate any preparation of cotton cellulose (other than cellulose esters), the chemical properties of which have been altered to a greater or less extent by the action of acids. The present position with regard to the scientific significance of the term "hydrocellulose" has been clearly stated by Hess[10] and the literature has been summarised by Clifford[5] and others.

The work described in this paper is limited to a study of hydrocelluloses which still retain the characteristic structure of the cotton hair, and it is not to be assumed without other evidence that the observed relations can properly be applied to more highly degraded preparations. Damage caused in technical practice by the action of acids upon cotton is generally confined to a partial loss of strength, and the powdery hydrocelluloses obtained by more drastic treatment have therefore received little attention in the present work, though evidently they cannot be so dismissed in any complete scientific study of the subject.

For an examination of the properties of hydrocelluloses which should form the basis of a routine analytical procedure, it was necessary to prepare a large number of cotton samples which had suffered from the attack of acids to different extents and under a variety of conditions. The methods which were originally described by Girard[8] for the preparation of hydrocellulose consisted (i.) in treating cotton with excess of a concentrated mineral acid at ordinary temperatures, (ii.) in submitting cotton to the action of a moist gaseous halogen hydracid, and (iii.) in allowing cotton which carried about its own weight of a dilute mineral acid to "dry" at the ordinary temperature, and subsequently heating it for various times at

40–70° C. Of these, the third method of preparation has frequently been used by later investigators, but the preparative conditions with respect to acid concentration, time, and temperature of treatment, are ill-defined—hence less reproducible—and the concentration of the acid which occurs on the material at an elevated temperature easily results in undesirable and profound cellulose degradation. A wide range of acid-modified celluloses can, on the other hand, readily be obtained under reproducible conditions by the action upon cotton of a large excess of acid at temperatures between 20° and 100° C. The formation of hydrocellulose by the action of heat upon cotton containing relatively small quantities of dilute acid is of practical importance, since damage suffered by cotton in technical processes, when it occurs through the action of acids, is frequently due to this cause, but for a systematic study of the properties of hydrocelluloses, such a method of preparation adds further to the complication of the problem. In this paper many hydrocelluloses are described, prepared both by steeping cotton in excess of acid of different concentrations at temperatures between 20° and 100° C., and by the action of dry heat upon cotton impregnated with small quantities of dilute acid; hydrocellulose formation induced by the former treatment will for convenience be referred to as the result of "acid steeping," and by the latter method as the result of "acid drying."

The fall in the tensile strength of cotton caused by the action of acids under any conditions of treatment is accompanied by a fall in the viscosity of the material when dissolved in cuprammonium hydroxide and by a rise in its reducing power, or copper number. These changes, occurring simultaneously, are not exclusive effects of acid action, since other chemical agents (oxidising agents) are capable of producing the same qualitative changes, but it was considered possible that a measure of the relation between any two quantitative properties of modified cellulose might point the way to a more precise analytical definition of hydrocellulose than any which has yet been given. The first part of this work deals therefore with the inter-correlation of different properties of hydrocellulose.

It is shown that for hydrocelluloses formed under a wide range of different conditions there exists a definite relation between loss of tensile strength and viscosity; in other words, that the same fall of viscosity corresponds to the same loss of strength irrespective of the precise mode of acid tendering. As a guide to the significance of the viscosity measurement, it may be noticed, for example, that acid attack, which causes the viscosity ($\log \eta$) to fall to the value 1, produces a loss of 10% in strength, whilst a loss of 80% in strength corresponds to a viscosity ($\log \eta$) of -1. These figures are taken from measurements of the single-thread breaking load of a standard 40's Egyptian yarn, but within the limits of experimental error they apply equally well to single-hair breaking load. As the strength of yarns depends upon twist and of fabrics upon structure, no general relation can be laid down between viscosity and mechanical tendering, save in a qualitative way, but the present results suffice to establish standards for judging, from measurements of viscosity, the extent of mechanical injury caused by hydrocellulose formation. Since a fall of viscosity to the value 1 caused by the action of acids upon cotton is accompanied by a 10% loss of strength in a particular normal trade product, it cannot be considered over-cautious if, until further information is available, this value of the viscosity is defined as a minimum permissible standard in any cotton materials.

A definite relation also exists between the strength and the copper number of the hydrocelluloses examined, a diminution of 10% in breaking load corresponding to a rise of 0·25 in copper number, and a decrease of 80% in breaking load to a rise of 3·5. Since, however, the copper number is greatly reduced by alkali boiling under conditions which have but little effect upon the viscosity, the latter measurement is more generally useful for the detection and estimation of acid tendering.

From an examination of about seventy different hydrocelluloses prepared by the widest possible range of acid action, it is shown that a given viscosity always corresponds to the same copper number irrespective of the conditions of acid treatment, and the relation between the two quantities can be expressed with reasonable accuracy over the most important range by a simple equation (p. T154). A specific analytical test or definition of hydrocellulose formation is to be found in the rise of copper number relative to the fall of viscosity, which in cases of true hydrocellulose formation conforms with the equation referred to above. By this means it is frequently possible to differentiate sharply between hydrocelluloses and those oxycelluloses which are otherwise indistinguishable from them. The exact relation between the copper number and viscosity of hydrocelluloses appears to vary slightly in comparing modified preparations originating from different samples of cotton. The cause of this variation has not yet been ascertained, but it is not sufficient to confuse the distinction between hydro- and oxycelluloses.

The results so far summarised refer to hydrocelluloses formed by the steeping treatment, but the viscosity-copper number relation has also been shown to hold approximately for hydrocellulose formation by the acid-drying treatment, provided the temperature of heating is not too high (70° C. or below), though the accuracy is here considerably less owing to the inferior uniformity of the material. At higher temperatures reactions occur other than that properly described as hydrocellulose formation, and the observed relation no longer holds.

The action of acids upon cotton is accompanied, in general, by a decrease in its affinity for basic dyes, but exceptions are made by sulphuric and phosphoric acid solutions of high concentration, either under steeping conditions or when the acid is allowed to concentrate upon the material by the action of heat at temperatures above the normal; in both cases there results an increased affinity for basic dyes. These facts have long been recognised qualitatively, and it was recorded by Witz[16] that when cotton fabric is steeped at ordinary temperatures for 20 hours in sulphuric acid containing 670 grams per litre, it dyes a slightly deeper shade with Methylene Blue than the untreated cloth, whilst with sulphuric acid, containing 840 grams per litre, immersion for a few hours results in very deep coloration on subsequent dyeing with the basic dye. Quantitative measurements have been made of the Methylene Blue absorption of many hydrocelluloses formed both by steeping and drying treatments, and it is shown that with sulphuric acid solutions of increasing concentration an initial fall of absorption, which is the normal result of acid action, is followed by a rapid rise when the concentration passes a certain value. The enhanced absorption of Methylene Blue by cotton which has been treated with sulphuric or phosphoric acid was ascribed by Harrison[9] to "a peptised form of hydrocellulose, or an adsorption compound of peptised cellulose with substances of a reducing

character," and similar views have been expressed in the most recent literature (*cf.* Schwalbe[14]). The incorrectness of Harrison's conclusions became probable when Knecht and Thompson[11] showed that the absorbing hydrocelluloses contained sulphuric acid in some unknown combination which could not be broken by boiling with dilute alkalis, though this observation appears to have been overlooked by later writers. The results of the present work fully confirm those of Knecht and Thompson, and in the case of phosphoric acid, where a very convenient analytical method is available, it has been shown that the Methylene Blue absorption is proportional to the acid content of the hydrocellulose. There can now be no doubt but that the enhanced absorption of sulphuric and phosphoric acid hydrocelluloses is due to combined acid which cannot, however, be completely removed by the most drastic alkaline treatments. The most certain analytical method for establishing the existence of damage sustained by cotton materials in technical practice, due specifically to the presence of traces of sulphuric acid during a drying process, would undoubtedly be a micro-determination of sulphuric acid which could compare in simplicity with that available for phosphoric acid. Further examples are given which show how the enhanced absorption due to oxycellulose formation may be distinguished from that due to the action of phosphoric or sulphuric acid, by absorption measurements made from acid Methylene Blue solution (*cf.* previous communication, "The Absorption of Methylene Blue from Buffered Solutions"[4]).

A knowledge of the rate of attack of cotton by acids under various conditions must be considered of equal practical importance with the analytical behaviour of hydrocelluloses, and the second part of this paper is concerned with the quantitative effects of temperature and concentration upon the rate of acid attack. For normal hydrocellulose formation, the copper number can be taken as a true measure of the extent of cellulose degradation, and it is shown that under conditions of acid steeping the increase of copper number with increasing time of treatment is governed by the rule that the copper number is increased by 50% when the time of treatment is doubled. The expression of this rule in the form of an equation enables a constant to be calculated—the velocity constant—which measures quantitatively the rate of attack of any definite acid solution at a definite temperature, and the effect of both acid concentration and temperature upon the velocity constant has been examined in a number of cases. The mean temperature coefficient of hydrocellulose formation over the range 20°–100° C. is found to be 2·3, which means that the copper number resulting from a given acid treatment is increased 2·3-fold by a 10° rise of temperature. With the addition of comparatively few experimental data to this section it would be possible to calculate with considerable accuracy the copper number resulting from the steeping of cotton in hydrochloric or sulphuric acid solution of any concentration for any length of time and at any temperature between 20° and 100° C., and a reasonable approximation can already be made from the recorded figures; since both viscosity and tensile strength have been related to copper number, these quantities could also be calculated.

The addition of neutral salt to a dilute solution of hydrochloric acid is shown to have a very great effect in increasing the rate of acid attack when the salt concentration becomes high, and attention is called to the possible importance of this effect in the action of concentrated zinc or magnesium chloride solutions upon cotton, where high neutral salt concentration is accompanied by slight acidity due to the hydrolysis of the salt.

DETAILED DISCUSSION OF RESULTS

PART I.—PROPERTIES OF HYDROCELLULOSES

I.—Breaking Load and Viscosity

Measurements are recorded in Table I. both of the single thread and the single hair breaking loads of twenty hydrocelluloses prepared by steeping the standard yarn No. 70C in acid, and the relation between these strength measurements and the viscosity of the modified celluloses in cuprammonium solution is shown graphically in Fig. 1. The ordinate scales corresponding to the two curves in the figure have been displaced relatively to each other in order to separate the curves and obtain greater graphical clarity. The conditions under which the individual members of this hydrocellulose series were prepared varied widely, as may be seen from the table, both sulphuric and hydrochloric acids being used in concentrations varying from 0·01*N* to 14*N*, at temperatures of 20° C. and 100° C., and for duration of treatment varying from 0·25 to 48 hours. In spite of this wide range of conditions the viscosity-strength relationship is represented by a single smooth curve within the limits of the experimental errors, and this is the case whether the strength is measured by the single-thread or by the single-hair breaking load.

The variation of viscosity with the breaking load of cotton which has suffered chemical attack by acids has been studied by Farrow and Neale[6] and others, the original contribution offered by this section of the present investigation lying in the proof which it furnishes that the relation between the strength and the viscosity of acid-tendered cotton is independent of the exact mode of tendering within the wide limits described.

The strength of a yarn is dependent not only upon the strength of the hairs which compose it, but also upon the frictional forces between them

and the single-thread breaking load is to this extent a more complex quantity than the single-hair breaking load. It was therefore to be expected that a different relation would exist between viscosity and breaking load for single threads from that obtaining for single hairs, but Fig. 1 shows that *in the particular case examined* such difference is scarcely greater than the experimental errors of breaking load measurement, the two curves being almost coincident when allowance is made for the relative shift in the ordinate scales.

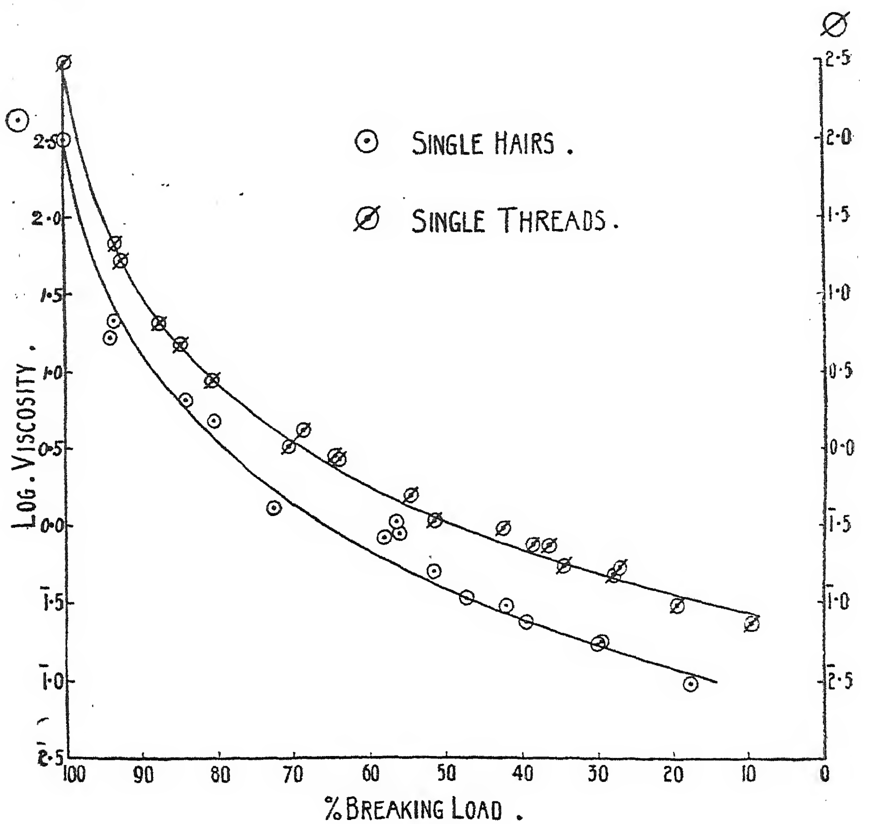

FIG. 1

II.—Breaking Load and Copper Number

The copper numbers of the hydrocelluloses described in Table I. are plotted against single-hair and single-thread breaking loads in Fig. 2, and here again all points lie on or near a smooth curve irrespective of the conditions of hydrocellulose formation. The figure shows that copper number, as a measure of tendering, is most sensitive in the later stages of acid attack where the loss of breaking load is between 50% and 100%, whilst the viscosity (Fig. 1) is most sensitive as a measure of strength changes in the early stages of acid attack which correspond to the first 20% loss in breaking load.

III.—Viscosity and Copper Number

(*a*) *Hydrocelluloses formed by Acid Steeping.*

The copper numbers and viscosities (log η) of a large number of hydrocelluloses prepared from the standard yarn No. 70C are recorded in Table II.

and the values are plotted against each other in Fig. 3 for as many of these preparations as can be represented in one diagram without sacrificing its clarity. The hydrocelluloses described were all prepared by the action of excess of acid (steeping experiments), but under otherwise very diverse conditions of treatment, concentrations varying from 0·05 to 700 grams per litre, temperatures from 20° C. to 100° C., and times of treatment from 0·25 to 960 hours; sulphuric and hydrochloric acids were used for most of the preparations, but results are given for three experiments with acetic

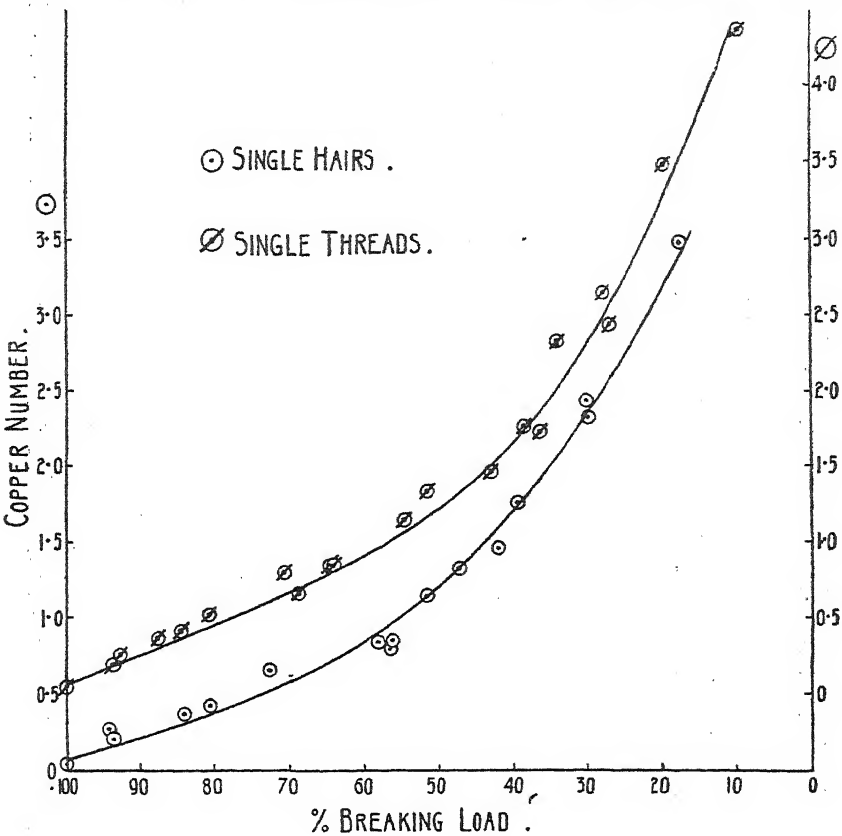

FIG. 2

acid. It can be seen from Fig. 3 that in spite of the wide variation in preparative conditions, all points lie on or near the same smooth curve, a result which can also be expressed by the statement that in this series of acid-tendered cottons a given copper number always corresponds to the same viscosity irrespective of the conditions of acid treatment. The viscosity and copper number are two properties of hydrocelluloses which are susceptible of the most simple and accurate measurement, and the widest range of data has therefore been collected and examined in this section.

The oxidation of cotton cellulose under certain conditions leads to the formation of modified material which resembles hydrocellulose very closely, but for these so-called oxycelluloses the viscosity-copper number relation is very different from that obtained for acid-tendered cottons. The points representing such oxycelluloses in Fig. 3 do not fall upon the curve, and

a distinction can be drawn between cotton cellulose modified by acids and that modified by the action of oxidising agents. Examples of this will be given later, but a detailed comparison of the viscosity-copper number relation for hydro- and for oxy-celluloses is left to a future communication.

If the relation between copper number and viscosity is to be used as a definition of hydrocellulose formation, or as an analytical test for acid attack of cotton, it must for convenience be expressed in the form of an equation relating the two measurements. Such an equation, which, for practical utility, must combine simplicity and reasonable accuracy, can be

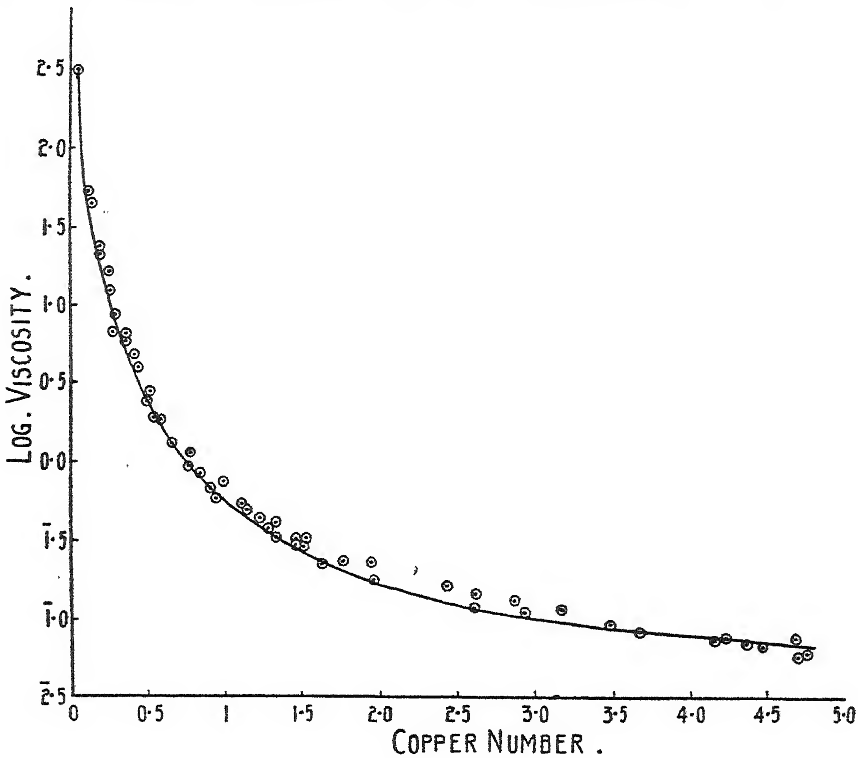

FIG. 3

obtained by a slight alteration in the method of expressing the viscosity measurement. In work from these laboratories the logarithm of the absolute viscosity is the quantity which has hitherto always been employed to characterise modified celluloses, but for the purpose designed above it is found more convenient to use the logarithm of the viscosity of cellulose or modified cellulose *relative to that of the solvent.* If η is the absolute viscosity of a 2% modified cellulose solution, and η_0 is the absolute viscosity of the cuprammonium solvent (taken as 0·0152 poise), then η/η_0 is the relative viscosity of the solution and the quantity log η, generally used in work on modified celluloses, will be replaced by log η/η_0, which will be designated by the symbol V, thus—

$$V = \log \eta/\eta_0 = \log \eta - \log \eta_0 = \log \eta + 1{\cdot}82.$$

In order to obtain V, the logarithm of the relative viscosity, it is only necessary to add 1·82 to the recorded values of the logarithm of the absolute

viscosity ($\log \eta$). If copper number is denoted by the symbol N_{Cu}, then the viscosity-copper number relation for the hydrocelluloses described in Table II. is represented with fair accuracy by the equation—

$$N_{Cu}V^2=2{\cdot}6.$$

In the table the hydrocelluloses are arranged in order of increasing copper number, the product $N_{Cu}V^2$ has been calculated and is recorded for each preparation, and it can be seen that for values of the copper number lying between 0·4 and 3·0, the product is reasonably constant, the mean value for 42 preparations being 2·6. For hydrocelluloses with copper numbers outside these limits the product $N_{Cu}V^2$ becomes less than 2·6, but the range within which the equation is valid is technically the most important and corresponds to loss of tensile strength (breaking load), varying roughly between 15% and 75% that of the untendered material used in this work.

Table III. contains the copper numbers, viscosities, and the product $N_{Cu}V^2$ for a series of oxycelluloses previously described,[2] covering the same range of copper number as the hydrocelluloses of Table II. These were also prepared from the standard yarn No. 70C by the action of hypochlorous acid and by other means could not be distinguished with certainty from hydrocelluloses, but the values of the product $N_{Cu}V^2$ leave no doubt that the modification is in this case not due to acid attack.

A shorter series of experiments has been carried out in which the standard yarn No. 70C was replaced by a standard bleached cloth No. 182, and the results, which are recorded in Table IV., can also be used to illustrate the relation between the viscosity and copper number of hydrocelluloses; some preparations made with phosphoric acid are included in this series.

These acid-treated cloths are also characterised by a sensibly constant value for the product $N_{Cu}V^2$ over a considerable range of copper numbers, the value being, however, somewhat higher than that obtained for the hydrocelluloses of Table II., namely, 2·9 compared with 2·6.

For comparison with these data, Table V. gives the properties of oxycelluloses formed from the cloth No. 182 by the action of hypochlorous and of chromic acids. These oxidised preparations were not distinguishable in individual properties from hydrocelluloses, but it is seen that the product $N_{Cu}V^2$ is not constant and is in all cases much greater than the value obtained for hydrocelluloses. The results, stated in their simplest qualitative form, show that a given copper number produced by the acid attack of cotton is accompanied by a much lower viscosity than when the same copper number results from oxidising attack. This conclusion applies only to oxycelluloses which possess no greatly enhanced Methylene Blue absorption.

(*b*) *Hydrocelluloses formed by Acid Impregnation and Heating.*

Certain inherent difficulties which are encountered in attempting to obtain reproducible results by drying dilute acids upon cotton materials at elevated temperatures render the measured properties of these hydrocelluloses of less intrinsic quantitative value than measurements made on hydrocelluloses formed by steeping cotton in excess of acid. Values are recorded in Table VI. for the copper number and viscosity of preparations obtained from the standard cloth No. 182 by impregnation with dilute acids and subsequent heating under different conditions, the range of copper numbers covered being approximately the same as in the corresponding series of steeping experiments made with this cloth (Table IV.). When the temperature of drying is not above 70° C. the value of the product $N_{Cu}V^2$ is roughly constant

and equal to that which characterises hydrocelluloses formed by steeping in excess of acid; much greater constancy cannot be expected in view of the difficulty of obtaining uniformly modified material by this method. There can be no doubt, however, that when the temperature of drying is high, the product $N_{Cu}V^2$ is not constant. The low values resulting from these more drastic treatments probably indicate other changes than the formation of the primary product of cellulose hydrolysis. One such change, which is discussed in a later section, is the combination between cellulose and acid, which results in the formation of hydrocelluloses possessing a high

Methylene Blue absorption. This reaction, super-imposed upon normal hydrocellulose formation, has occurred to a considerable extent in a number of the preparations described in Table VI., particularly those formed at higher temperatures. It is also probable that further cellulose degradation to soluble cellulose dextrins or sugars occurs to an increasing extent with increasing severity of the acid drying treatment. The formation of such soluble reducing products is proved by the fact that the copper numbers of the hydrocelluloses in Table VI., determined without previous washing with water, were from 15% to 50% higher than the recorded values, which were all obtained from washed preparations. The simultaneous occurrence of these reactions is sufficient to explain the complete failure of the viscosity-copper number relation when applied to the preparations obtained by acid impregnation followed by heating at the higher temperatures.

IV.—The Methylene Blue Absorption of Hydrocelluloses

Measurements have been made of the Methylene Blue absorptions of most of the hydrocelluloses, some properties of which have already been tabulated. Absorptions determined in buffered solutions (preceding memoir) will alone be recorded in this paper, but the results are supported by a large number of unrecorded measurements carried out by the original method[1] using unbuffered Methylene Blue solution.

(a) Hydrocelluloses formed by Acid Steeping.

Table VII. records the Methylene Blue absorptions of hydrocelluloses formed by steeping cloth No. 182 in sulphuric acid solutions of increasing concentration for 48 hours at 20° C.

Table VII.

Cloth 182, Steeped in Sulphuric Acid at 20° C. for 48 hours.

Preparation No.	182	SC36	SC37	SC38	SC39	SC40	SC41	SC42
Concentration of H_2SO_4, grams per litre	0	100	200	300	400	500	600	700
Methylene Blue Absorption—								
At *p*H 7	0·89	0·82	0·83	0·82	0·79	0·79	0·94	1·30
At *p*H 2·7	0·31	0·28	0·26	0·25	0·27	0·36	0·72	1·76

Increasing concentration of sulphuric acid causes at first a steady fall in the Methylene Blue absorption of the untreated cloth, but this attains a minimum value at a certain acid concentration beyond which the absorption increases rapidly. The rise begins at a concentration of sulphuric acid from 500 to 600 grams per litre when absorptions are measured with unbuffered or *p*H 7 buffered Methylene Blue solutions, but as described in the previous paper ("Absorption of Methylene Blue from Buffered Solutions"), the effect is greatly enhanced when the dye solutions are acid, and at *p*H 2·7 the rise in the absorption begins at a concentration of sulphuric acid from 400 to 500 grams per litre.

When hydrocelluloses covering a similar copper number or viscosity range to those of Table VII. are prepared by the action of sulphuric acid at considerably higher temperatures, and consequently at much lower concentrations, no rise of absorption is observed, but only the steady fall which characterises the earlier members of the series described above. This is the case for example when cotton is steeped for an hour at 100° C. with sulphuric acid solutions up to a concentration of 0·5*N*, the absorption falling to approximately half that of the untreated material—considerably lower than the minimum values in Table VII., where the initial fall is to some extent masked by the subsequent rise.

The same steady fall of absorption with increasing modification is observed when cotton is steeped in hydrochloric acid *under any conditions*, whether at 20° C. for concentrations up to 300 grams per litre, or at 100° C. for concentrations as high as 0·2*N*. There can be no doubt that a decreasing absorption is the normal accompaniment of the acid attack of cotton, an enhanced absorption being a peculiar property of hydrocelluloses formed by the action of relatively high concentrations of sulphuric or other oxy-acid. The preparations described above, characterised by high Methylene Blue absorption, and formed by steeping cotton at 20° C. in sulphuric acid solutions of concentration greater than 600 grams per litre, were found to contain sulphuric acid which they retained with remarkable tenacity, and it will be shown conclusively in the next section that high absorption is due to this retention of mineral oxy-acid.

(*b*) *Hydrocelluloses formed by Acid Impregnation and Heating.*

Table VIII. gives the Methylene Blue absorptions of hydrocelluloses prepared by impregnating cloth No. 182 with dilute sulphuric acid solutions of various concentrations, and subsequently heating for two hours at four different temperatures. The preparations heated at 50° C. show exactly the same behaviour as the hydrocelluloses of Table VII., prepared by steeping in relatively concentrated acid at 20° C., namely, an initial fall of absorption followed by a rapid rise as the concentration of sulphuric acid increases, this rise beginning at an acid concentration from 0·1*N* to 0·5*N*. At 70° C. the rise is already well marked at an acid concentration of 0·1*N*, whilst at

90° and 110° C. the measurements at *p*H 2·7 show a greatly increased absorption with acid as dilute as 0·025*N*. It will again be observed that the rise of absorption is more sharply defined and relatively much greater in measurements made from the acid (*p*H 2·7) than in those made from the neutral (*p*H 7) Methylene Blue solution.

below that of the untreated cloth, though under the most drastic conditions—N acid at 90° C. or 0·1N acid at 110° C.—a definite rise of absorption occurs. This rise is only shown, however, by preparations which have suffered far-reaching degradation, and it differs from that which characterises the sulphuric acid preparations, inasmuch as it is relatively smaller in measurements made from acid than in those made from neutral Methylene Blue solutions.

In order to determine the cause of the high absorption of certain hydrocelluloses, a series was prepared by impregnating and drying cloth with a dilute phosphoric acid solution. For this acid, which is known to cause increased absorption of Methylene Blue similar to that produced by sulphuric acid under the same conditions, a rapid and accurate method of analysis is available (Geake[7]). The Methylene Blue absorptions of hydrocellulose formed by impregnating cloth No. 182 with 0·1M phosphoric acid, and heating for two hours at temperatures between 50° C. and 130° C., are given in Table X., which includes the phosphoric acid content of the preparations after prolonged water washing.

Table X.

P. 7	130° C.	1·82	2·14	3·31

It will be seen that, with respect to Methylene Blue absorption, the behaviour of this series of hydrocelluloses is the same as that of similar preparations made with sulphuric acid, the absorption rising with increasing

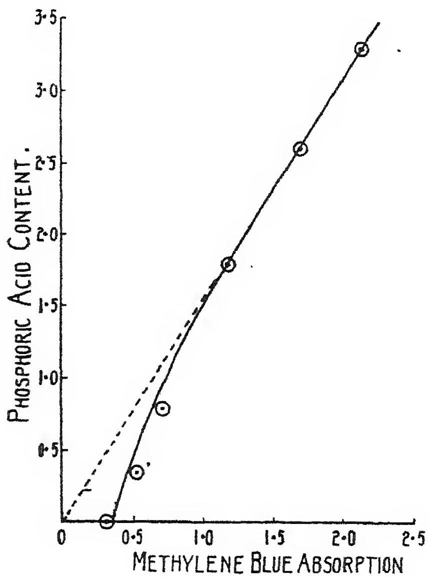

Fig. 4

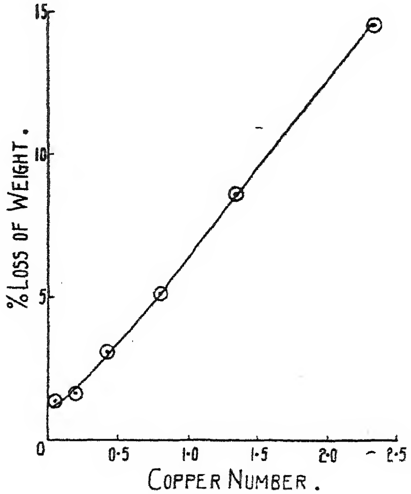

Fig. 5

temperature, more rapidly from acid than from neutral Methylene Blue solution. Associated with this rising absorption is a steady increase in the phosphoric acid content of the preparations, and Fig. 4 shows that the Methylene Blue absorption from solution at *p*H 2·7 is proportional to the phosphoric acid content of the hydrocellulose except in the early stages where this relation is disturbed by the initial absorption of the untreated cotton; the straight line which represents this proportionality in the latter stages passes very close to the origin of co-ordinates and corresponds therefore to a zero absorption when the phosphoric acid content is zero. The results which have been described prove conclusively that when high Methylene Blue absorption results from the action of sulphuric or phosphoric acid upon cotton it is due to the retention of acid and cannot be regarded as a property of hydrocellulose, as this term is defined in an earlier section. Attempts to free the preparations described in Table X. from phosphoric acid, even by the most drastic alkaline treatments, were only partially successful, as shown in the following table.

V.—Behaviour of Hydrocelluloses on Boiling with Dilute Alkali

It is known that hydrocelluloses are decomposed to a greater or less extent by boiling dilute alkalis, yielding soluble decomposition products, and experiencing therefore a certain loss of weight. Table XII. shows the losses of weight sustained by a series of hydrocelluloses prepared from the yarn No. 70C by steeping in sulphuric acid solutions of various concentrations for 48 hours at 20° C., and it also compares the properties of these hydrocelluloses before and after alkali boiling; for the determination of loss of weight the samples were boiled with 1% sodium hydroxide solution for four hours, but for examining the effect of alkali boiling upon the properties of the hydrocelluloses they were submitted to a technical kier boil of six hours' duration with 1% sodium hydroxide at 20 lbs. excess pressure, a process which produced appreciably greater loss of weight than the analytical procedure.

In Fig. 5 the losses in weight are plotted against copper numbers, and over the range examined the relation is approximately linear, the percentage loss in weight being roughly six times the copper number; this relation is almost the same as that observed for oxycelluloses within the same copper number range,[2] but considerable deviations undoubtedly occur both with hydro- and oxy-celluloses of higher copper number. It is concluded that copper number and loss of weight on alkali boiling have the same analytical significance, but the determination of copper number is greatly to be preferred on grounds of both speed and accuracy. The loss of weight of the untreated material (the "blank") is a very uncertain correction, owing to the indiscriminating nature of the measurement, and is relatively high for slightly modified material.

Table XII.

Sulphuric Acid Hydrocelluloses boiled with Dilute Alkali.

Preparation No.	% Loss of Weight	Copper Number		Log Viscosity in 2% Solution		Single Thread Breaking Load % on Untreated Material	
		Before Boiling	After Boiling	Before Boiling	After Boiling	Before Boiling	After Boiling
70C	1·40	0·04	0·03	2·5	2·03	100	105
36AB	1·69	0·205	0·01	1·33	1·20	93·3	97·8
37AB	3·06	0·425	0·06	0·69	0·40	84·7	84·2
38AB	5·14	0·80	0·08	0·02	$\bar{1}$·91	70·3	67·5
39AB	8·66	1·34	0·21	$\bar{1}$·53	$\bar{1}$·56	51·4	43·0
40AB	14·7	2·32	0·39	$\bar{1}$·23	$\bar{1}$·22	34·1	24·2
41AB	—	3·48	0·56	$\bar{2}$·98	$\bar{1}$·00	19·5	12·1
42AB	—	4·36	0·98	$\bar{2}$·85	$\bar{2}$·85	9·7	5·5

The copper number is in all cases greatly diminished by alkali boiling and would evidently approximate to zero after sufficiently prolonged treatment, but the viscosity is only slightly affected, remaining unchanged for the more highly modified members of the series and suffering a slight fall in the case of the less modified members. The difference of behaviour in this respect is more apparent than real on account of the great sensitiveness of the viscosity to changes in the material in regions of high viscosity.

The effect of alkali boiling upon the single-thread breaking load of hydrocelluloses is not great until the loss of weight becomes considerable, and the less modified preparations suffer no change or actually show an increased strength after kier boiling, due no doubt to swelling of the cellulose and tighter binding of the component hairs in the yarn.

This single series of hydrocelluloses has alone been examined with respect to its behaviour on alkali boiling, but since the copper number-viscosity relation shows that hydrocelluloses prepared under a great variety of other conditions are in nature identical with these, it can be assumed with confidence that they behave in the same way on alkali boiling.

PART II.—RATE OF ACID ATTACK OF COTTON

I.—Copper Number and Time of Treatment

The rates of attack of cotton under two different acid treatments could be compared by means of the copper numbers which result when the two treatments are continued for equal times, but this is not always convenient, since a duration of treatment which produces an intermediate copper number under one set of conditions often produces barely measurable or extremely far-reaching degradation under the other set with which it is to be compared. When the copper number resulting from the action of acid under definite conditions of steeping has been determined for any one time of treatment, it is found possible, however, to calculate the copper number resulting from any other time of treatment within the range of cellulose hydrolysis to which these investigations are restricted. This can be done by means of the rule which is found to hold with fair accuracy that when the time of action of a given acid treatment is doubled, the copper number of the resulting hydrocellulose is increased by 50%; thus, if in one hour a certain acid treatment of cotton results in a copper number of 1, in two hours it produces

a copper number of 1·5 and not of 2 as would be the case if the copper number were proportional to the time of action. This relation between copper number and time of acid action is closely expressed by the equation—

$$N_{\mathrm{Cu}}=KT^{0\cdot 6}$$

where N_{Cu} symbolises copper number, T the time of treatment, K being a constant under definite conditions of acid treatment (concentration, temperature). In view of the empirical nature of the copper number measurement, no theoretical significance can be attached to the form of this relation. If the time is measured in days the constant of the equation gives directly the copper number which results from the acid treatment continued for one day. When the copper number which corresponds to any time of treatment is known, substitution of the values in the equation enables K, the copper number after one day's treatment, to be calculated directly, and the test of the accuracy of the above equation is to be found in the agreement between the values of K obtained by substituting a number of different values of the time T, and of the corresponding copper numbers N_{Cu}. This test has been applied to the data given in Tables XIII., XIV. and XV., which record the rate of change in copper number of the standard yarn No. 70C when steeped in sulphuric or hydrochloric acid solutions of various concentrations and at different temperatures, and it will be seen that the value of K is sensibly constant for each set of conditions.

The mean value of K derived from a series of experiments covering a range of copper numbers, as illustrated in the tables, is the best measure of the rate of attack of a given acid solution under definite conditions of concentration and temperature. For the calculation of this constant, which will be called the velocity constant, values of the copper number above 4 have not been used, since such values approach the upper limit set by the routine analytical method employed.

II.—Effect of Concentration of Acid upon Rate of Attack of Cotton

The rate of attack of cotton, measured by the velocity constant, is given in Table XVI. for hydrochloric and sulphuric acids over a range of concentrations at three different temperatures. The velocity constants have been calculated from single observations in a number of cases, whilst in others they have been directly determined as the copper number resulting from one day's acid treatment, neither procedure being as accurate as that described in the last paragraph, where the constant is evaluated from a series of observations.

Table XVI.

	Velocity Constant K	1·74	3·33	5·92	21·3	—

For the purpose of comparing the activities of the two acids with respect to rate of hydrocellulose formation, concentrations are expressed in molarities, and in Fig. 6 the rate of acid attack of cotton at 20° C. is plotted against concentration of hydrochloric or sulphuric acid; in Figs. 7 and 8, similar curves are given for both acids at 40° C. and 100° C. respectively. These curves show that at any temperature the rate of hydrocellulose formation is approximately the same for solutions of the two acids of equal molar concentration (not equivalent solutions), hydrochloric acid being, however, always slightly more active than sulphuric acid. The velocity constant at 20° C. and 40° C. is almost proportional to the acid concentration for values below 3 molar, but for increasingly rising concentrations above this value the curves become increasingly steeper, as shown in Figs. 6 and 7, that is,

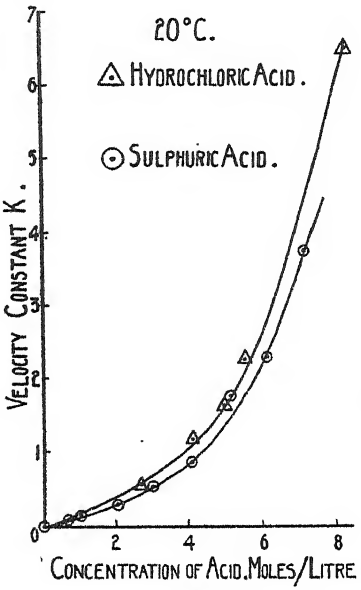

Fig. 6

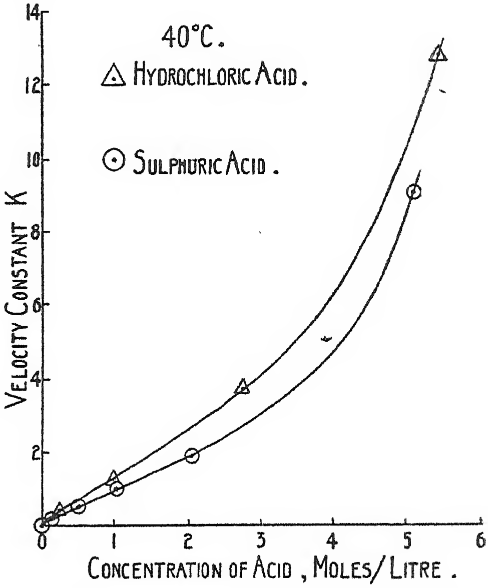

Fig. 7

the rate of attack increases much more rapidly than the acid concentration; thus the activity of 8-molar hydrochloric acid at 20° C. is nearly six times that of 4-molar acid. It is not possible to examine the shape of the curves at 100° C. for such high acid concentrations, since the velocity constant at this temperature would be of the order of several hundreds, and the rate of attack would thus be too rapid for accurate measurement.

III.—Effect of Temperature upon the Rate of Acid Attack

The temperature coefficient of the rate of hydrocellulose formation as measured by copper number can be calculated from the velocity constants already recorded over the temperature range 20° C. to 40° C. for sulphuric acid at concentrations of 0·5*M*., 1·02*M*., and 2·04*M*., and for hydrochloric acid at a concentration of 2·74*M*., the values being 2·2, 2·5, 2·4, 2·5 respectively for a 10° interval. The coefficient can also be calculated, though with less accuracy, over the higher temperature ranges 60° C. to 100° C. for 0·1*M* hydrochloric acid (using a determination of the velocity constant at 60° C. given in the next section), and 40° C. to 100° C. for 0·1*M* sulphuric acid; the result is 2·2 in both cases. The average value obtained is thus 2·3,

which means that the copper number resulting from the action of a given solution of either acid acting for a definite time is increased approximately 2·3 fold by a 10° rise of temperature within the range 20° C. to 100° C.

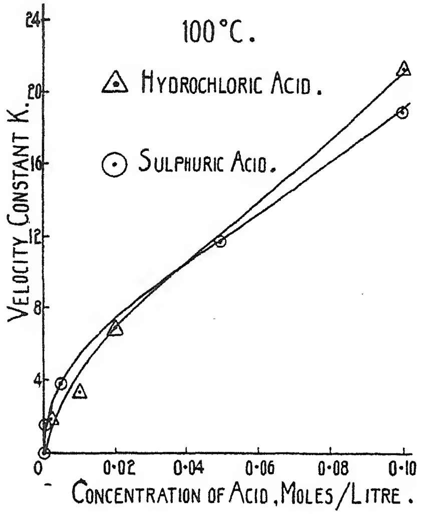

Fig. 8

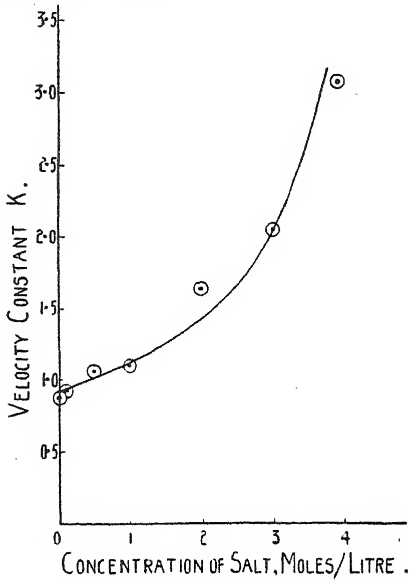

Fig. 9

IV.—Effect of Neutral Salt upon Rate of Acid Attack

It has been found that high concentrations of sodium chloride very greatly increase the activity of hydrochloric acid, and Table XVII. records the velocity constants for the action of 0·1*M* hydrochloric acid at 60° C. upon the yarn No. 70C in the presence of increasing concentrations of sodium chloride.

Table XVII.

Effect of Sodium Chloride upon Rate of Attack of Yarn 70C. by 0·1*M* HCl at 60° C.

Concn. of NaCl ...	0	0·1	0·5	1	2	3	3·9 Molar
Velocity Constant K	0·87	0·92	1·06	1·10	1·63	2·04	3·05

A very great effect is observed, the rate of attack of the dilute acid being increased over threefold by making the solution 3·9*M* in sodium chloride (roughly three-quarters saturated). In Fig. 9 the velocity constant is plotted against the salt concentration, and the resulting curve is similar in shape to those of Fig. 6, the rate of attack at high salt concentrations increasing much more rapidly than the concentration of the salt. It seems probable that these observations have an important bearing upon the action of concentrated solutions of zinc or magnesium chloride upon cotton. The acidity of these solutions, which is a consequence of the hydrolysis of the salt, is not considerable, but its effect may be greatly enhanced by the high concentration of neutral salt.

V.—Rate of Attack when Cotton is Impregnated with Dilute Acid and Heated

The rate of attack of cotton materials which contain dilute acid on drying at elevated temperatures is not capable of very systematic treatment owing to variations in the acid concentration which necessarily occur during the process, but qualitatively, at least, the progress of acid attack is very

different from that which distinguishes hydrocellulose formation by excess of acid of constant concentration.

Table XVIII. records the copper numbers which result when cloth No. 182 is impregnated with three different acid solutions and heated at constant temperature for various times. It is remarkable that with both sulphuric and phosphoric acids, after a short period, continued heating produces only a very slow rise of copper number, and it has also been observed that the fall of viscosity is very slow after the initial effect. The rise of copper number caused by doubling the time of treatment does not exceed 10%, and in most cases is very much less, whilst it will be remembered that in the acid steeping experiments the effect of doubling the time of treatment was to increase the copper number by 50%. Since the acids are not appreciably volatile at temperatures up to 110° C., the conclusion appears unavoidable that acid is *consumed* in reactions other than true hydrocellulose formation.

Table XVIII.

Cloth 182, Impregnated with Dilute Acids and Heated for various Times.

Concn. of Acid	Temperature of Heating	Time of Heating :—	0·33	0·5	1	2	4 hours
H_2SO_4 2N	40° C.	Preparation No.	—	A17	A18	—	—
		Copper Number	—	2·25	2·49	—	—
H_2SO_4 0·5N	70° C.	Preparation No.	A16	A10	—	A9	—
		Copper Number	4·26	4·49	—	4·57	—
H_3PO_4 0·1M	110° C.	Preparation No.	—	P8a	P8b	P8c	P8d
		Copper Number	—	1·28	1·34	1·46	1·52

Similar conclusions must be drawn from an examination of the temperature effect, and Table XIX. records the copper numbers of hydrocelluloses formed by the impregnation of cloth No. 182 with dilute sulphuric and phosphoric acids, with subsequent heating for two hours at temperatures ranging from 50° C. to 130° C. With increasing temperature the copper number rises to a maximum, and beyond this point temperature has little or no effect upon the copper number, behaviour very different from that observed in the steeping experiments where a rise of 10° C. increased the copper number 2·3-fold. It has been observed that the viscosity continues to fall slowly with rising temperature, so that the product $N_{Cu}V^2$ also falls, an effect which has already been noted and which is well exemplified by the phosphoric acid preparations already described in detail in Table VI.

Table XIX.

Cloth 182, Impregnated with Dilute Acids and Heated for 2 Hours at various Temperatures.

Concn. of Acid	Temperature of Heating :—	50°	70°	80°	90°	110°	130° C.
H_2SO_4 0·5N	Preparation No. ...	A11	A9	—	—	—	—
	Copper Number ...	3·79	4·57	—	—	—	—

	Copper Number ...	0·74	1·23	—	1·55	1·45	1·67

There is thus considerable evidence that hydrocellulose formation by the method under discussion is accompanied at the higher temperatures by other reactions which result in an actual consumption of acid, and which, like all other cellulose degradations, are accompanied by falling viscosity without, however, any great change of copper number. One such reaction is, no doubt, that fixation of sulphuric or phosphoric acid which subsequently produces hydrocelluloses with an enhanced Methylene Blue absorption.

Hydrochloric acid occupies a unique position in this series of experiments on account of its volatility, the normal increase of rate of attack with temperature being counterbalanced by the rapidly increasing volatility of the acid. The result of these conditions is that the copper number of cotton impregnated with dilute hydrochloric acid and heated increases at first with rising temperature, passes through a maximum, and then falls again as the temperature and volatility of the acid become high. From Table XX. it will be seen that the maximum copper number is reached at about 70° C. both with 0·1*N* and 0·025*N* hydrochloric acid, and a solution of the latter concentration can be heated in contact with cotton at 90° C. without producing significant tendering, whilst the same acid at 70° C. causes loss of strength of the order of 70%.

0·025*N*	Copper Number ...	0·96 ...	2·56 ...	0·10 ...	0·20

EXPERIMENTAL METHODS

(A) Preparation of Hydrocelluloses

(i.) *Steeping in Acid at* 20° *C. and* 40° *C.*—Cotton was added to the acid in a thermostat in the proportion of 40 grams of the former to 1 litre of the latter, care being taken to ensure thorough wetting. The concentration of acid was usually controlled by titration against standard sodium hydroxide, but in some cases the more concentrated solutions were made up to the required specific gravity. After removal from the acid the hydrocellulose was washed with distilled water and air-dried, but when concentrated sulphuric acid solutions were used, the hydrocellulose was dipped in a diluter solution before washing with water, in order to avoid any appreciable rise of temperature.

For the measurement of yarn and hair breaking loads, special precautions were necessary in sampling the material, and the following "cut-skein" method was therefore adopted (Midgley and Peirce[13]). Two leas of yarn were wound from a hank and cut at the two ends of a diameter, being first tied with string at each side of the cuts in order to prevent untwisting; one half of the two leas was treated with acid and the other retained as a control. From the remainder of the hank two bundles of threads of about three inches length were obtained by cutting through the skein, and 1,000 normal hairs were taken from one of these by carefully untwisting 100 threads and selecting ten hairs from each. These hairs were submitted to the acid treatment together with the yarn, and from the remaining three-inch bundle of threads hairs were taken in the same way and preserved as

controls. The portion of the hank still remaining, and further hanks as might be necessary, were treated and used for the various chemical tests.

Treated hairs were thoroughly washed on a filter plate with distilled water and immersed overnight in water to which a drop of dilute ammonia solution was added; they were then again washed, pressed between filter paper, and air-dried. The adequate removal of acid from treated yarn or cloth necessitated, however, more prolonged washing, and although a nearly neutral wash-water could soon be obtained, this offered no guarantee that acid had been eliminated from the interior of the material. The following washing method was finally adopted for hydrocelluloses prepared from yarns or fabrics. The preparation after removal from the acid was washed once or twice by decantation with distilled water and centrifuged in a "hydro-extractor" running at 2,000 r.p.m. and having an ebonite basket of $5\frac{3}{4}$ inches diameter, the water content being thus reduced to about 100% of the dry weight of the material. It was then washed in the hydro-extractor twelve times to complete the removal of surface acid, and steeped in 25 times its weight of distilled water. After standing a day the wash water was tested, the hydrocellulose centrifuged, washed three times in the hydro-extractor, and again steeped. This process was repeated until, for three days in succession, the water after steeping was not more than $10^{-5}N$ in mineral acid, and the hydrocellulose was then dried by exposure to the air at room temperature. The wash waters were tested with Methyl Red (*p*H 4·2 to 6·3), and occasionally by measurement of electrical conductivity, the following figures, which were obtained after treatment of a 40's yarn with sulphuric acid at 700 grams per litre, being given to illustrate the progress of washing.

Time after removal from acid	1 hr.	3 hrs.	1 day	2	4	5	6	7	8 days
No. of wash water ...		First		2nd	3rd	4th	5th	6th	7th
Specific conductivity in reciprocal ohms ...	7·2	13·3	29·3	9·4	12·4	12·0	5·7	6·4	5·0

The final figures correspond approximately with the conductivity of $10^{-5}N$ sulphuric acid.

This process did not eliminate the acid completely, and a number of determinations of sulphuric or hydrochloric acid in normal hydrocelluloses possessing no enhanced Methylene Blue absorption gave results varying between 0·03 and 0·2 milli-equivalents per 100 grams. These small quantities of acid were insufficient to cause damage during short storage, and the figures given below illustrate the stability of a preparation washed in the manner described.

	Copper Number	Log Viscosity
Hydrocellulose No. S.T. 5—Freshly prepared	2·61	$\bar{1}$·09
,, ,, After storage for 12 months ...	2·64	$\bar{1}$·07

(ii.) *Boiling with Acid*—Cotton was boiled with about 50 times its weight of standard acid under the reflux condenser with occasional shaking. All the solutions used were too dilute to have boiling points appreciably different from that of pure water. When $0{\cdot}001N$ acids were employed it was essential to reduce the ash alkalinity of the cotton by shaking for an hour at room temperature with $0{\cdot}1N$ sulphuric acid and washing to neutrality, since otherwise the acid was completely neutralised during the boiling. Hairs for the measurement of breaking load were boiled at the same time in a separate small flask.

(iii.) *Impregnating with Acid and Heating*—Considerable difficulty was encountered in obtaining significant measurements of the properties of hydrocelluloses formed by impregnating cotton with dilute acid solutions, drying, and heating the material at an elevated temperature. This difficulty arose from the fact that the acid attack did not occur uniformly over or through the material, and the correlation of measurements made on different samples from the same preparation was for this reason of uncertain value. The following method was finally adopted: Cotton in the form of cloth was thoroughly wetted out in a large volume of the acid and repeatedly mangled between rubber rollers until the weight was double the air-dry weight ($2\frac{1}{4}$ times in the case of phosphoric acid solutions); it was then allowed to "dry" overnight in the air and heated on a rotating glass frame inside an electric oven maintained at the required temperature for the necessary length of time. This procedure yielded reasonably uniform and reproducible results when the concentration of acid was not less than 0·025*N*, but with acid as dilute as 0·01*N* no method was found which yielded uniform results over a considerable area of cloth. The cotton was in all cases washed with cold dilute acid and water before impregnation and heating, in order to reduce the ash alkalinity to as low a value as possible, but even after this treatment the residual ash alkalinity varied from 0·5 to 1 milli-equivalent per 100 grams, and when 0·01*N* acid solutions were used the amount of acid present on the cloth (1 milli-equivalent per 100 grams) was thus of the same order of magnitude as the residual ash alkalinity. The irregular results which were obtained with very dilute acids can only be ascribed to irregular distribution of the residual ash with consequent partial and non-uniform neutralisation of the acid by it.

The washing process which followed the acid treatment was somewhat less rigorous than that described above, and some measurements of copper number were also made on the unwashed material.

(B) Methods of Measurement

(i.) *Breaking Load*—A number of measurements made on samples prepared in the course of this work have been published recently by Vincent[15] and these are utilised here. Additional determinations of yarn-breaking loads were made on a Goodbrand Single Thread Tester, using 40 cm. lengths and at a constant temperature of 20° C., and relative humidity of 70%. Each hydrocellulose was compared with the corresponding control sample obtained as already described, the individual controls from the same batch of hanks differing considerably from one another in mean breaking load. Single threads of the tendered and untendered control samples were examined alternately, 150 breaks being observed on each, and this number was sufficient to reduce the probable error to a small value.

Hair-breaking loads were measured with an improved O'Neill apparatus[12] at a constant temperature of 20° C. and relative humidity of 66·3%, 200 breaks being observed on each tendered and control sample. All hydrocellulose breaking loads are expressed as percentages on those of the untreated control specimens.

(ii.) *Copper Number*—Braidy's method was used, the details being as recently described.[3] Samples weighing 2·5 grams were taken for analysis and results are expressed as grams of copper reduced per 100 grams of dry material. Good agreement was obtained between duplicates, except when the copper number was very high.

(iii.) *Viscosity*—The viscosity of hydrocelluloses in cuprammonium solution was estimated by the method of Farrow and Neale.[6] Results are recorded for 2% solutions, and when the viscosity was very high these values were calculated from measurements made in weaker solutions, as described in the paper referred to above.

(iv.) *Methylene Blue Absorption*—This was measured on 2·5 gram samples by the titrimetric method already described, using buffered Methylene Blue solutions of *p*H 7, and in some cases acetic acid solutions of *p*H 2·7[1,4]. The results are expressed as millimols of Methylene Blue absorbed per 100 grams dry material.

(v.) *Loss of Weight on Alkali Boiling*—The procedure described by Birtwell, Clibbens, and Ridge[2] was adopted.

(vi.) *Phosphorus Content*—This was determined by the method already described.[7] In order to avoid loss of phosphoric acid by volatilisation, the sample for analysis was moistened with dilute sodium carbonate solution before ignition.

(C) Material Used

With a few exceptions, the hydrocelluloses formed by the acid steeping process were prepared from a 40's combed Sakel warp yarn (No. 70C), spun with standard twist, which had been technically scoured with 1% sodium hydroxide solution for six hours at 20 lb. excess pressure.

Hydrocelluloses formed by acid drying and a few by acid steeping were prepared from a cloth of American cotton (No. 182) which had been scoured for eight hours with 1% sodium hydroxide at 40 lb. excess pressure and lightly chemicked.

16—THE COTTED FLEECE

By J. A. FRASER ROBERTS, M.A., B.Sc.

(Animal Breeding Research Department, University of Edinburgh.)

INTRODUCTION

During the last three years the writer has been engaged on a study of the fleece of the Welsh Mountain sheep in connection with a scheme of wool improvement put forward by the University College of North Wales, Bangor, and carried out in conjunction with the Animal Breeding Research Department, University of Edinburgh. His attention was particularly directed to the problem of the cotted fleece by Mr. King and Mr. Frobisher, of the British Research Association for the Woollen and Worsted Industries, and the samples collected from the Welsh Mountain pedigree sheep of the College flock appeared to provide suitable material for a study of the condition.

MATERIAL

The "cotted" fleece in its extreme form is well known to those who deal with wool in its raw state. The cotted fleece is closely matted together usually fairly near the skin, and considerable force has to be exerted in order to tear it apart; the writer is informed that such fleeces are sometimes so closely matted that they can be used as rugs. A badly cotted fleece is definitely much less valuable than a similar normal fleece. The examination of numerous samples soon showed that there is often a tendency for the same matting to occur in a much less severe form, and that in fact it is possible to obtain a complete series ranging from fleeces that are heavily cotted down to fleeces that show just the faintest indication of a line of cotting when a staple is spread out. Only the very heavily cotted fleece would be described as such in the trade sense, but a study of the lightly matted variety is of value in determining the nature of the process involved and also in determining the possible causes that lead up to the condition. In 1920, 1923, 1924, and 1925, 246 samples were available, taken at shearing time from the pedigree Welsh Mountain sheep mentioned. In 181 cases there was no indication of cotting; in 65 cases there was at least some trace of it. For the sake of convenience it was necessary to form some estimate of the severity of the cotting in any particular case. The 65 samples (nearly all taken from the shoulder) were accordingly arranged in order of severity of cotting as far as this could be judged by eye and feel. The samples were then classified into grades, Grade 1 representing the most heavily cotted condition, Grade 5 the least. It is probable that only those fleeces placed in Grade 1 would be technically described as cotted; in 1924, Mr. James Briggs, who graded the pedigree wool, classed five fleeces as cotted, and it was found after the above classification had been effected that these five fleeces had all been placed in Grade 1 and that no other fleece of the 1924 clip had been placed in that grade. The Plates I. to IV. show samples of various cotted fleeces, and in each case the grade of cotting is noted. The cotting may be exhibited right at the bottom of the staple, as shown in Plate II., Fig. 2, or may be as high as that shown in Plate II., Fig. 1. It is also an important point that in none of the 65 cases examined did cotting occur twice during the year.

THE NATURE OF THE PROCESS THAT RESULTS IN COTTING

The examination of samples of cotted fleeces has led to the conclusion that the formation of the matted area is due to the shedding from their follicles of a proportion of the wool fibres. If all, or nearly all, the fibres are shed, the fleece is, of course, shed as a whole, as is sometimes seen. If, however, it is only a proportion that is shed, continuity is maintained. Before the shedding actually takes place the fibre becomes considerably reduced in diameter; this thin terminal portion which is extremely convoluted becomes intertwined round the similar convoluted terminal portions

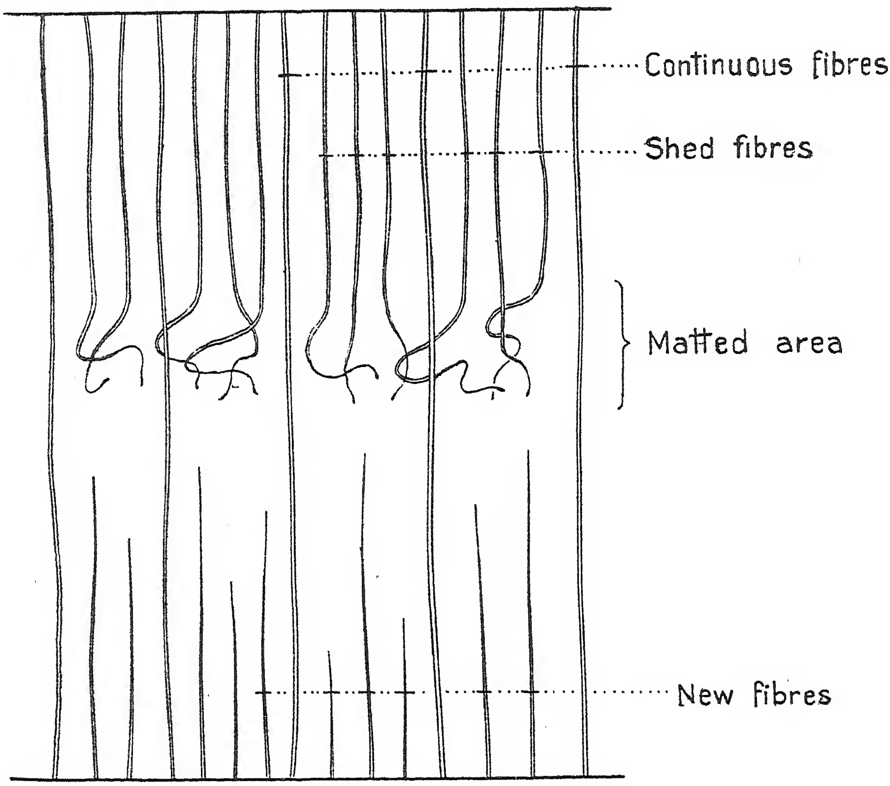

FIG. 1

of other shed fibres, and so the mat is produced. Later new fibres appear and it is difficult to determine whether or not their fine whip-lash tips also become involved in the network; probably they do not to any extent, but the point is of little practical importance, as it does not affect the main contention that cotting is due to a partial shedding of the fibres composing the fleece. The matted area is often particularly rich in wool grease, but its removal by means of ether does not destroy the mat. There may or may not be a certain amount of loosening after this treatment—the point is difficult to determine simply by inspection and handling—but the fact undoubtedly remains that any effect of the increased production of wool grease in binding the fleece together at the cotted line, if it exists at all, is subsidiary to the actual intertwining of the fibres. The text-figure indicates diagrammatically

the nature of the process. The evidence on which the above conclusion is based will now be presented—

1—The great majority of samples from cotted fleeces show a difference in density, *i.e.* in the number of fibres above and below the cotted line, the area proximal to the cotted line being definitely less dense than that distal to it. This can only mean that a proportion of the fibres terminate in the cotted area. If a fair proportion of the staple is proximal to the cotted line, it is seen that there is a gradual increase in density in the proximal direction; again, this can only mean that a new growth of fibres is taking place. The samples shown in the plates illustrate these points very well; it is most clearly seen in those cases where the severity of the cotting is moderate, but even in the sample shown in Plate I., Fig. 2, which exhibits the highest grade of cotting, the same situation can be made out. Plate IV., Fig. 1, is specially instructive; in the case of this sheep most of the fleece had been shed in patches before shearing and in the sample photographed continuity is only maintained by a small proportion of fibres.

2—Attempts to dissect cotted samples confirm the above conclusion. Fibres that are continuous throughout the length of the staple can easily be pulled out. They are not tangled in the mat and they provide the basis for continuity; but for this, the fleece would, of course, be shed as a whole. If the bottom of the staple below the cotted line is firmly clamped down it should be possible to pull out fibres terminating in the cotted area which would show the little terminal bulb that indicates that shedding has taken place. In practice this is not easy, owing to the fragile nature of the terminal portions and to the fact that they are involved in the network; however, it has been found that with care fibres can be pulled out in this way which actually show the little terminal bulb when examined under the microscope. Similarly, if the sample is clamped down above the cotted area, the tips of new fibres, complete with whip-lash ends, can be pulled out.

There is no reason to doubt that cotting of whatever grade of severity depends essentially on the same process. A complete range without discontinuity anywhere can be obtained, and also, as mentioned above, the process can be traced directly even in such a heavily cotted fleece as that shown in Plate I., Fig. 2. There need therefore be little hesitation about the applicability of observations made on the more lightly cotted samples to those which would be termed cotted in the trade sense.

THE TIME OF YEAR AT WHICH THIS PROCESS OCCURS

Certain preliminary work carried out by the writer would seem to show that the rate of growth of the fleece is remarkably uniform. This observation makes it possible to arrive at an estimate of the time of year at which cotting occurs by an examination of samples taken at shearing time. Work on these lines is being carried out at present, and is in much too elementary a stage for any definite conclusions to be stated, but as long as it is realised that the assumption of a uniform growth-rate is tentative, it is useful to attempt to discover whether the cotting process tends to occur at any particular period and to determine the limits of that period. For this purpose the length of each sample (only those taken from the same point, the shoulder, were considered) was measured, together with the distance from the cotted line to the tip of the staple and to the bottom of the staple. Assuming, therefore, a uniform growth rate and allowing one centimetre for the length

of the wool left on the sheep, and knowing the dates of shearing, a percentage value was calculated as follows—

$$\frac{(\text{Length from cotted line to bottom of staple}) + 1{\cdot}0 \text{ cm.}}{\text{Total length of staple}} \times 100$$

As the dates of shearing were practically identical in the years considered, the total length of the staple represents a year's growth, 8·3% of the total representing a month's growth. If, for example, the result of the calculation above were 25%, it would indicate that the process occurred three months before the date of shearing. Of course, this method is only applicable in the case of shearings after the first. The results of an examination of 48 samples were as follows—

Table I.

Month during which process occurred	No. of cases
November	1
December	3
January	9
February	26
March	6
April	3

It should be noted that there are possible sources of error, as already indicated, which might result in this estimate giving rather too early or too late a period as the critical one. In addition, there are a few sources of error that might affect individual values, *e.g.* a few sheep might have been trimmed for show or in the case of a fleece that was nearly shed the attenuated portion of the staple would tend to be stretched out, but these individual errors are not likely to be important.

The data can also be examined with reference to another important point, viz., whether the critical period occurs at different times in different seasons. The results for the years 1923, 1924, and 1925 are as follows—

Table II.

Month during which Cotting occurred	No. of Cases 1923	1924	1925
November	1	—	—
December	1	1	1
January	3	4	2
February	6	13	7
March	4	1	1
April	—	3	—

A mathematical examination of these figures shows that the differences between the three years are not significant.

With regard to the yearling fleeces it is much more difficult to estimate the period at which cotting occurred. The exact dates of birth of the individual sheep are not known, the lambing period being spread over perhaps six weeks, and in addition some lambs are born with a coat which is already of appreciable length, while others possess a much shorter one. There is some indication in the case of these fleeces that cotting occurs slightly earlier on the average, but for the reasons given not much stress can be laid on this result. It may be concluded with fair certainty that the cotting process occurs during winter and spring, and that the great majority of cases occur during a limited period which is probably about February. There does not appear to be any appreciable difference in the time of occurrence of this period from year to year, at least as far as the three years under review are concerned.

THE SIGNIFICANCE OF AND THE POSSIBLE CAUSES UNDERLYING THE PARTIAL SHEDDING OF THE FLEECE

An examination of the data makes it possible to answer three additional questions that have a close bearing on the problem of the occurrence of the cotted fleece.

Is the Tendency to Produce a Cotted Fleece Constitutional?

In the case of 57 sheep, samples were available for two consecutive years. In the first year 23 of these were cotted. If there were no constitutional tendency towards cotting, the proportion of cotted fleeces in the second year should be the same in the case of the 23 sheep which were cotted in the first year, as it is in the 34 which were not cotted in the first year. Actually in the second year 13 of the 23 fleeces previously cotted were again cotted, and of the 34 not previously cotted only four. This is a clear indication that the tendency to produce a cotted fleece is to some extent characteristic of certain individual sheep. Such a sheep will not infallibly produce a cotted fleece, but will be more likely to do so than the average. Of the 13 fleeces cotted in both years, seven showed a higher grade of cotting in the second season; three showed the same grade; and three a lower grade. There does therefore seem to be a tendency for a sheep which possesses a cotted fleece to exhibit in a subsequent year a more severely cotted fleece. The figures, however, are small and many more observations are required fully to substantiate this point.

Has Cotting or the Degree of Severity of Cotting any Relation to the Age of the Sheep?

The facts are presented in the following table—

Table III.

Age of Sheep in Years	Cotted Fleeces										Fleeces not Cotted	
	Grade 1		Grade 2		Grade 3		Grade 4		Grade 5			
	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age
1	1	1·2	2	2·3	—	—	2	2·3	9	10·5	72	83·7
2	2	3·8	2	3·8	—	—	4	7·5	4	7·5	41	77·4
3	—	—	—	—	2	4·6	3	7·0	5	11·6	33	76·8
4	1	3·0	4	12·1	1	3·0	4	12·1	3	9·1	20	60·7
5	1	5·1	2	11·1	1	5·1	3	16·6	2	11·1	9	50·0
6	1	9·1	—	—	1	9·1	1	9·1	3	27·3	5	45·4
7	—	—	—	—	—	—	—	—	1	50·0	1	50·0

To obtain a clearer view of the situation, grades of cotting 1–3 and 4–5 are grouped together in the following table—

Table IV.

Age of Sheep in Years	Percentage Cotted Fleeces: Grades 1–3	Percentage Cotted Fleeces: Grades 4–5	Percentage Fleeces not Cotted
1	3·5	12·8	83·7
2	7·6	15·0	77·4
3	4·6	18·6	76·8
4	18·1	21·2	60·7
5	21·3	27·7	50·0
6	18·2	36·4	45·4

It will be seen that there is a well marked tendency for cotting to increase with the age of the sheep. This is, however, only an average. For example. one sheep only one year old shows the highest grade of cotting. The figures are too scanty to support a very detailed analysis, and it is only possible to indicate the probability that cotting becomes more severe as well as more frequent in older sheep. The chief effect of age appears to be, however, to increase the number of cotted fleeces.

Is there any Variation from Season to Season in a given Flock in the Proportion of Sheep with Cotted Fleeces?

Comparable figures are available for the seasons 1923, 1924, and 1925.

Table V.

Season	Cotted Fleeces										Fleeces not Cotted	
	Grade 1		Grade 2		Grade 3		Grade 4		Grade 5			
	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age	No. of sheep	Per-cent-age
1923	—	—	2	3·0	2	3·0	8	12·1	17	25·8	37	56·1
1924	5	5·5	6	6·6	2	2·2	5	5·5	7	7·7	66	72·5
1925	1	1·4	2	2·8	1	1·4	4	5·5	3	4·2	61	84·7

Again, for convenience, a shortened table is given in which grades of cotting 1–3 and also 4–5 are grouped together.

Table VI.

Season	Percentage Cotted Fleeces Grades 1–3	Percentage Cotted Fleeces Grades 4–5	Percentage Fleeces not Cotted
1923	6·0	37·9	56·1
1924	14·3	13·2	72·5
1925	5·6	9·7	84·7

There is an undoubted variation from season to season in the proportion of sheep exhibiting cotted fleeces. It will be seen that in 1923 and in 1925 the percentage of sheep with cotted fleeces of Grades 1–3 is low. In 1924 and in 1925 the percentage of sheep with cotted fleeces of Grades 4–5 is very low compared with the corresponding figures of 1923. It can be concluded that 1925 was a good year for absence of cotting and 1924 a bad one, especially as regards the higher grades. The figures for 1923 require a little additional explanation; of the 29 sheep shown as cotted in that year, no less than 12 were yearlings and the fleeces of these sheep with one exception all fell into Grades 4 and 5. In 1924 only three yearlings had cotted fleeces, and in 1925 none. The heavy percentage of lightly cotted fleeces in 1923 is largely due therefore to the fact that in that year some factor was operating which particularly affected the yearlings. Fourteen samples taken from the yearlings in 1920 were also available for examination, and in this case too none were cotted.

The considerations that have been discussed make it possible to gain some insight into the nature of the influences responsible for cotting and into

their mode of action. First of all, the evidence seems to point clearly to what may be called a "susceptible period." If it were possible for the action of external influences to induce cotting at any time, it is most improbable that not a single case in which the process took place in summer or autumn should have been found. In addition, the extreme limits in time during which the process was found to have occurred are wide, and there is no reason mechanically why cotting should not occur twice in the same individual during a single season unless the assumption is made that each sheep is only susceptible during a limited period to the external or internal influences that are responsible for the partial shedding of the fleece. It need not be maintained that for the cotting process to occur in summer or early autumn is an absolute impossibility. This may or may not be true, but there is considerable reason for holding that if such a result were obtained it could only be due to some extraordinary condition or method of treatment quite outside the normal range. A note of caution should perhaps be struck here; the data refer to a single flock and it is just conceivable, though most improbable, that the management of this flock might be responsible for this result. The sheep receive practically no food other than grass, and therefore the period of greatest shortage would occur about February, March, and the beginning of April. If such an explanation is adopted it is difficult to account for the fact that cotting does not occur twice within a single season. In any case, the discussion is intended to be suggestive and not a conclusive argument in favour of a definite hypothesis.

Another most significant fact is that although there are wide seasonal variations in the proportion of sheep in the flock possessing cotted fleeces, the period of the year during which the process has taken place does not vary appreciably. Again, it is difficult to account for this unless the existence of a susceptible period is assumed. If such a period did not exist, it would be difficult to explain why the influences responsible for the cotted fleece should show such wide variations in intensity from season to season, and at the same time always act at the same period of year (and for the most part within such narrow limits). It is known that there occurs in the Welsh Mountain breed as in many others a phenomenon known as the "rise" in the wool, which is characterised by the fibres composing the fleece becoming finer in diameter, though few would normally be shed. Until work has been carried out which will furnish an exact description of this process, and in particular define the limits in time during which it occurs, it is impossible to form any very rigid conclusions relative to the possible relationship of the rise to cotting. That there is some relationship is probable, and it is quite reasonable to imagine that some factor or factors operative at the time of the thinning might push the process further and so a partial shedding would result. The analysis has so far led to the recognition of an individual tendency towards cotting which is certainly constitutional and probably hereditary, a tendency that becomes more marked with age; secondly, the analysis indicates a susceptible period spread over several months in the case of the whole flock though confined to a fairly limited period as far as the majority of cases are concerned, and probably there is also an indication that the susceptible period in the case of any individual sheep is confined to a short and definite period. (The data are unfortunately insufficient for any answer to be given to the question as to whether the time of year is the same in the case of an individual sheep in which the process occurs in successive years.)

It is perhaps not very profitable to speculate at any length as to the exact nature of the influences which act on a susceptible individual at the susceptible time, but a few considerations may be mentioned. These factors vary considerably from season to season and might be nutritional, climatic, or connected in some cases with pregnancy, which in the case of ewes bearing lambs terminates about the time at which the process occurs. It is not improbable that the rhythm in the growth of the fleece, as shown, for example, by the rise in the wool corresponds to a rhythm in the general metabolism of the sheep, and such a factor as thyroid activity is just the sort of mechanism that might be anticipated. The "external" stimulus to cotting might well be due to influences, *e.g.* nutrition that result in variations in thyroid functioning. It might be mentioned that in the case of this particular flock, at least dipping had nothing to do with the cotting process. In no case were the sheep dipped in the period during which the process occurred. The writer has examined fleeces that have been said to have been "damaged" by dip, but these were not cotted; tensile strength, &c., may have suffered, but in most cases the most obvious phenomenon was only a deposit of adherent material on the surface of the fibres. The writer has also had, however, the opportunity of examining very heavily cotted fleeces from a flock where the cotting was universal and unquestionably due to dipping, but this was an exceptional case; the sheep had been dipped for a particular purpose repeatedly at short intervals and *during the susceptible period.*

In conclusion, it may be stated that any research that had for its object the discovery of all the factors that result in cotting, and the search for methods of prevention, would fall naturally into two groups—

1—An analysis of the hereditary tendencies involved, *i.e.* the question as to whether cotting could be eliminated by the weeding out from the flock of certain individuals.

2—A determination of the environmental and physiological factors involved, a study that would depend on both observation and experiment. In fact, the apparently simple problem of cotting leads on naturally to the physiology of the growth of the fleece in the widest sense.

The writer wishes to express his thanks for helpful criticism and advice to Dr. F. A. E. Crew and to Professor R. G. White, of the University College of North Wales. He is also indebted to Mr. James Briggs, of Elland, who graded the fleeces in connection with the main scheme.

SUMMARY

(1) This study is based on the examination of samples from 246 fleeces from the pedigree Welsh Mountain flock of the University College of North Wales, taken in 1920, 1923, 1924, and 1925.

(2) For the sake of convenience, five grades of severity of cotting were arbitrarily fixed. Only the most severely cotted grade, 1, would correspond to the technical definition of cotting, but useful information can be deduced from samples which exhibit the same process at work to a lesser degree.

(3) Cotting is due to a shedding of some of the fibres composing the fleece, the fine terminal portions of such fibres becoming intertwined.

(4) The cotting process takes place in various individual sheep during winter and spring, but the great majority of cases occur during a comparatively limited period, which is probably about February. The time of the occurrence of this period does not appear to vary appreciably from year to year.

(5) The tendency to produce a cotted fleece is largely constitutional, *i.e.* is characteristic of the individual sheep. The proportion of sheep affected becomes greater with age, and also there are big variations in the proportion of cotted fleeces in the same flock from season to season. The evidence points to variable factors which act during a susceptible period on sheep of varying individual susceptibility. Such factors are probably intimately connected with the metabolism of the sheep.

17—COLOUR INHERITANCE IN THE WENSLEYDALE BREED OF SHEEP

By F. W. Dry, D.Sc.

(Department of Textile Industries, The University of Leeds.)

INTRODUCTION

In conducting breeding experiments with sheep, extending over several years, the temptation is to delay the publication of the results, year by year, until in fact the investigation is brought to a conclusion. Each lambing season, it is next year's results that one really wants. In the research now to be discussed, the original series of experiments, which has been in progress for the past three seasons, is not yet finished, being continued for at least the present breeding season, but the work has reached a point at which a new departure, aimed at practical results, has seemed justified. The object of this paper is to give a general account of the work done up to the present time.

In the Wensleydale breed, as is well known, a large proportion of black lambs are born, although black animals are not used for breeding. The actual percentage, including the small numbers of silver-grey lambs, is about 15%. The proportion is much the same as it has been for many years. The animal desired by Wensleydale breeders has the skin of the extremities of the body, especially of the head region, deep blue in colour. Some sheep are not as blue as the desired standard, just a few being very pale. An occasional ram used in a pedigree flock dose not sire a single black lamb, but has his entire family composed of whites. A few lambs are silver-grey rather than black, bearing a fairly even mixture of black and white fibres, but until the experiments are dealt with it will be enough to distinguish White and Black. These are the broad facts from which the investigation started. In the light of all that is known of colour inheritance in smaller animals, one could at once be sure that these facts would lend themselves to interpretation along Mendelian lines. At the outset, suggestions as to possible relationships between the different colour types could be made, but the truth of any hypothesis remained to be tested. The additional evidence needed has been secured in two ways. Firstly, the experience of breeders has been collected and flock records analysed. An account of what was learnt in this way has already been published.* Secondly, breeding experiments have been carried out, and though they seem to be nearing completion, are still in progress.

INFORMATION FROM BREEDERS AND FLOCK RECORD ANALYSES

The information obtained from breeders may be briefly reviewed. The most valuable data were supplied by Mr. G. Goland Robinson, who kept detailed records of the flock of Lord Henry Bentinck, M.P., at the Underley Farm, near Kirkby Lonsdale. Mr. Robinson's records covered the whole period during which this flock was maintained, from its foundation in 1897

J. Genetics*, 1924, **14.

to its dispersion in 1922. At the time this inquiry was taken in hand Mr. Robinson was Honorary Secretary of the Wensleydale Longwool Sheep Breeders' Association, and, as he has continued to do, gave every possible assistance. It has also been my privilege to visit a large proportion of the owners of registered flocks, and to meet most of the members of the Council of the Association again and again. When the organisation of the breeding experiments is explained, it will be shown again how many people have helped in this investigation.

First, a word may be said about the blue complexion. The great function of the Wensleydale breed, which numerically is a small one, is to provide rams for cross-breeding, a large proportion of all the males born being sold for breeding purposes. Mated with Black-faced Mountain ewes, rams with a deep blue complexion are stated to sire lambs with darker mottled faces than rams that are paler in complexion. Cross-bred lambs so marked are more in favour with butchers, giving, it is said, a higher proportion of lean meat. These are the statements of breeders, though it should be added that while the majority of those interested in a substantial way in cross-breeding attach this importance to the blue colour, this is not true of all. The possibility that these statements may be true cannot be questioned in view of analogous cases in smaller animals. On these points detailed studies are called for. In any case, the deep blue complexion certainly is the trade mark of the Wensleydale breed, distinguishing it in a striking manner from other longwools. One can sympathise with the feeling that from the standpoint of beauty the blue complexion is a distinct asset.

One piece of information which early came to hand was specially welcome, because it gave the result of a mating which would never be made in an ordinary flock, and had this mating not already been tried it must have been made in one of the first breeding experiments. Black Wensleydales mated together produce nothing but black lambs. Two gentlemen owning parks felt that flocks composed entirely of black sheep would present a pleasing appearance. Each flock was made up of typically black animals born in registered flocks. Mr. F. Samuelson, of Breckenborough Hall, near Thirsk, recorded sixteen lambs. For the facts about the other flock I am indebted to Mr. E. G. Howsin, Estate Agent to Colonel Starkey, on the Huntroyde Estate, at Padiham, near Burnley. This flock consisted each year of about forty ewes and was kept up for ten years. Many of the later breeding sheep, both ewes and rams, were born in the flock, others being added from pedigree white flocks. Some six hundred lambs were bred, none of them white, and none of them classified at birth as silver-grey. From the point of view of this investigation, each gentleman keeping a black flock was performing an essential experiment. In the case of the larger flock this experiment was carried out in a far more thorough-going manner than has been possible in any of the series started in 1922.

Whites can produce blacks. Blacks mated together give nothing but blacks. Clearly black is recessive to white. The question next arises, is Black a simple recessive, or are matters more complicated? If Black is a simple recessive, then when white animals that are all capable of producing blacks are mated together we should get in large numbers the well-known 3:1 Mendelian ratio, three whites to one black. Any white animal able to have black offspring at all would, when mated with blacks, give approximately equal numbers of whites and blacks, provided the numbers were

large enough for a sufficient test. If, however, we are concerned with two different Mendelian factors, so that Black is a double recessive, the numerical results in those matings would be different. Whites selected at random, all able to be the parents of black lambs, would, mated together, have fewer blacks than one in four in the aggregate. Whites mated with blacks would some, as in the other case, have half their lambs black, but others would give only one black lamb in four. On surveying the facts gathered from breeders one may well suppose Black to be a double recessive. Leaving out the families of the few rams that established all-white records, the proportion of blacks born is definitely less than one in four. At Underley, on almost three thousand lambs, the percentage of blacks was 20·8. Data from other sources give not quite 16%, on nearly four thousand lambs. Again, some rams have a larger proportion of blacks in their families than others. At Underley, in the offspring of those rams which sired a hundred lambs or more, the percentages of blacks varied from 16 to 29. Many a ram has been discarded because he was believed to be specially prone to bring black lambs. It is probably the general belief amongst breeders that differences in the percentages of blacks in the families of rams are due to inborn differences between the rams. Obviously, this is a question not solely of academic interest. Fortunately, the Underley records give a pretty clear answer to the question whether Black is or is not a simple recessive. This is obtained by the use of a simple statistical device in the study of the families of the individual ewes. In the light of this analysis, one may think of Mr. Robinson, in managing the Underley flock for a quarter of a century, and keeping complete records, as carrying out a long period breeding experiment which is fairly critical for the point under discussion. In making this analysis the lambs sired by a ram that never in a long career became the father of a black are regarded as non-existent, and the families of a small number of ewes are omitted where any lamb was the offspring of some ram that sired only a small number of lambs, and so, although the lambs were all whites, did not prove whether he was really able to beget a black. As five was the average number of lambs composing the family of a ewe, it inevitably came about that many ewes never had a black lamb. It is with those families that did include at least one black that we are concerned. The method of statistical treatment is that employed by Jones and Mason.* Suppose Black to be a simple recessive. For families consisting of one lamb and including a black, the proportion of blacks is necessarily 1. For families of two the proportion will be somewhat more than ·5 and so on, gradually approaching ·25 as the size of the family increases. For each size of family Jones and Mason calculate the expected number of recessives—in our case black lambs—from a modified Mendelian ratio which allows for the omission of all families not containing any such animal. The proportion is calculated from the formula—

$$X = \frac{1}{4\left[1 - \left(\frac{3}{4}\right)^{n}\right]},$$

where n is the number of offspring in the family. It will be seen from the table that the figures obtained from the Underley data agree very closely with expectation, and justify the conclusion that Black is a simple recessive.

If Black be a simple recessive, it follows that white Wensleydales may be divided into two classes—(1) Duplex or homozygous whites, sheep incapable of having black lambs even if mated with blacks, and (2) simplex or heterozygous whites, sheep that do have black lambs. Moreover, animals of the latter class if mated with blacks would all in the long run give approximately equal numbers of whites and blacks, any deviation from equality in small families being attributed to chance, just as in tossing pennies a small number of times the number of heads and tails may be by no means the same. These two types of ewes, we may be sure, exist in every flock of any size. Indeed, from the percentages of black lambs born we may calculate the proportion of duplex ewes. If 16% of the lambs are black and all the rams used sire some blacks, this means that four times 16%, or 64%, of the ewes can produce blacks and give the 3:1 ratio, and that the remaining 36% of the ewes can have only white lambs. Further, of the white lambs produced in those matings, where it is possible for blacks to be born, one-third will be duplex whites, while the duplex ewes being mated with simplex rams will give offspring half of them duplex, half simplex. Hence it may be calculated in the case under consideration that 34% of all the lambs born are duplex whites, or that of all the white lambs 40% are incapable of becoming the parent of a black. At Underley the proportions of duplex whites would be 17% amongst the ewes, and 29% of the total lambs, or 36% of the white lambs born. Two questions present themselves. Firstly, are we able to form any idea whether an untried animal can or cannot produce blacks? Secondly, if so many duplex ram lambs are born, how is it that so few are used in pedigree flocks? It may be said at once that there is no known method, other than a breeding test, of distinguishing with certainty between duplex and simplex whites. The difficulty of doing this will become very apparent when the results of the breeding experiments are given. Still, something has been learnt from the inspection of a number of rams with all-white records. Rather more than a score such animals have been heard of, most of them being no longer alive. I have examined eleven. Apart from the inside of the ears all these were blue enough in

impossible to find any fault with him on that point. One, while not the bluest of the blue there, did not fall far short. The rest in greater or less degree were on the pale side in this respect. Of the rams which died before I took up this work, those who used them say that a few were typically blue throughout, but several are said to have been somewhat pale inside the ears. Now, in selecting stock rams great importance is attached to colour within the ear. With so many animals from which to choose very few that are below standard in this respect find their way into pedigree flocks, although one or two such animals amongst those not siring blacks, thanks to other qualities, have been amongst the most successful sheep of their day in the show ring. The ewes, on the other hand, cannot be selected so keenly for colour. Two facts from the Underley records have bearing on this discussion. Firstly, the percentage of blacks born in that flock was distinctly higher than the average for the breed. Secondly, the percentage of blacks was substantially the same when the flock was dispersed as it was in the early years, in spite of the fact, of course, that all blacks were thrown out of the flock. Throughout the breed the endeavour is made to select for the blue complexion, but special attention was paid to this at Underley. It is, however, the case that some ewes most decidedly pale in colour inside the ears do have black lambs. Surveying all these points, it is safe to conclude that duplex whites are generally lacking in colour inside the ears, and that animals deep blue in that region are generally simplex whites. That is as far as one can go. In selecting for deep blue colour within the ears, breeders are keeping up the numbers of simplex whites, and so keeping up the numbers of blacks born, although blacks themselves are thrown out. In the case of the rams the selection can be very keen. With the ewes it is not possible to keep the colour standard so high, and many duplex animals are kept for breeding. In fact, in most flocks the proportion of gimmers taken into the flock that are simplex cannot be much higher than the proportion in all the gimmers born. This is the explanation adopted of the fact that the proportion of blacks born is less than one in four.

THE BREEDING EXPERIMENTS

When the results of the inquiries amongst breeders were tabulated Professor A. F. Barker, who has been interested in this colour problem for a long time, urged that no time should be lost in starting breeding experiments. The experiments were designed to explore further the relations between the colour types existing in the breed, their purpose being to test the views that had been formed, and to decide between alternatives where the available data did not warrant a definite opinion. A scheme was drawn up and discussed with the members of the Council of the Sheep Breeders' Association. The animals, mostly lent by some twenty breeders, were got together in the autumn of 1922. The experiments have been carried out by Mr. T. E. Clarke, at Challan Hall, Silverdale, Mr. A. G. Ramshay, at East Appleton, Catterick, and Mr. H. Stephenson, at Cowton Grange, Darlington. About seventy animals have in all been used for breeding. The first season most of the animals put to the ram were unavoidably only in their first year, and only a few lambs came along in the spring of 1923, but each of the last two seasons sixty or seventy lambs have been born. The expenses of the experiments have been met mainly by grants from the Ministry of Agriculture. The research as a whole has been supported chiefly by the funds of the Ackroyd Memorial Research Fellowship, with some

help from Clothworkers' Funds, at Leeds University. The general plan of the experiments has been to make those matings in which it was possible for the three colour types, White, Black, and Silver-grey to figure, about which information had not already been obtained, and to learn also something about the inheritance of complexion colour in white sheep. Animals which were not white were classed as black or silver-grey from the lamb fleece; typical examples of each were chosen. A summary of the results so far obtained is now presented.

I.—Experiments with Rams with All-White Records

(*a*) *Rams with All-White Records mated with Black Ewes.*—Two different rams which had established white records in Wensleydale flocks were used. *Bluebottle* sired 11 lambs, all whites, born in 1923. *Lundholme Pippin II.* was the father of 40 lambs, again all whites (1924). Both these rams were coppery in colour inside the ears. *Bluebottle's* lambs could all be classed as of good blue complexion, including the inside of the ears. The same is true of three-quarters of those by the second ram, but at the age of about four months four lambs resembled their sire in complexion and two were lighter still. Two of the former were used in Experiment (*b*), and retained until shearlings, and one of the two palest was also kept until a shearling. In all three the complexion showed no appreciable change.

(*b*)—*Two sons of Lundholme Pippin II. from the above experiment mated with Black Ewes*—The two rams resembled their father in being copper coloured inside the ears. The lambs were 27 whites and 20 blacks, including a few silver-greys by one ram, or approximately half and half (1925). The white lambs were many of them blue enough in complexion, but on the whole they were not a specially blue lot.

(*c*)—*Lundholme Pippin II. mated with White Ewes copper coloured inside the ears*—Ewes were chosen having complexions like that of the ram. Twelve white lambs resulted (1925). These included some darker and some lighter than the parents; on the whole they were light.

II.—Black Rams mated with White Ewes of very Pale Complexion

This mating was made each season, six different ewes having lambs. Sixteen white and two black lambs were obtained. Most of the whites were deep blue in complexion, but some were quite pale. The two blacks were both from the same ewe, the palest of the six.

III.—Silver-greys mated together

This mating was made every season, five different rams being used. There resulted 26 silver-greys and six blacks. No whites were born.

Two other experiments are now in progress. These matings are White × Silver-grey and Black × Silver-grey.

PRESENT POSITION DISCUSSED

The present position of the investigation may now be considered in the light of the breeding experiments. The results of these are consistent with the views adopted before, but it is upon the analysis of the Underley records, not upon the experiments, that the conclusion that Black is a simple recessive rests. The relation between the three colour types, White, Silver-grey, and Black, may be stated as follows. It is possible for whites mated together to produce all three types; this, of course, happens in white Wensleydale flocks. Silver-greys mated together have given mostly silver-greys, some blacks, no whites. Blacks mated together produced nothing but blacks.

The three types therefore appear to form an epistatic series, White dominant to Silver-grey, and Silver-grey dominant to Black. It is of practical importance to know that silver-greys mated together do not produce whites. At the outset the possibility was kept in mind that with silver-grey parents on both sides the offspring might consist of blacks, silver-greys, and whites of pale complexion in the ratio 1:2:1. Were that so, blacks mated with whites of pale complexions would be expected to give lambs all silver-greys. These results have not come about. The point is this. Had silver-greys given any whites, these, being recessive whites, could have been counted on to breed true, like black Wensleydales, and as the Albino does in so many species of animals. Could that be done we should have a simple way of establishing an all-white flock, but now we know that we cannot hope for anything in this direction. It is upon the duplex whites that attention must be concentrated. Which whites are duplex and which simplex, as has been stressed already, we cannot determine by sight, and this difficulty has been emphasised by the experience gained in the experiments.* To mention only the most striking fact, black lambs were produced by the white ewe with the palest complexion found in a special search for pale animals.

ATTEMPT TO ESTABLISH A PURE WHITE FLOCK

It now remains to describe briefly the new work taken in hand in the mating season of the autumn of 1925. This has for its aim the eventual establishing of a flock of duplex whites. All the animals chosen are at least a little pale in colour inside the ears. A score of ewes have been secured that in families of five or more have never had a black, and that by rams known to be able to sire blacks. Some of these ewes, as well as a couple of gimmer hoggs that have been included, are daughters of rams whose lambs have all been white. These animals have been divided between two elderly rams that have made good their all-white reputations. It is, of course, anticipated that all the lambs will be white. Some forty black gimmers have also been bought. These are nearly all hoggs, it being necessary to secure them a year in advance to prevent them from being sent to the butcher. In the autumn of 1926 the plan will be to mate some of the ram lambs with these blacks. A ram siring eight lambs all whites from black ewes is virtually certain to be a duplex white. In this way it is hoped to obtain by the summer of 1927 a small number of shearling rams which can be guaranteed never to sire blacks from any Wensleydale ewe. From the gimmer lambs a selection would be made of animals to be put in due course to rams known to be duplex whites, and so on with succeeding generations. The proportion of duplex whites in such a flock would be expected gradually to increase. The breeding tests of the rams would show what progress was being made. Rams brought into the flock must, of course, have established their claim to be duplex whites. Eventually, breeding on these lines, it can confidently be said that the trial matings could be dispensed with, and that after some years one could be satisfied that none of the animals in the flock could have a black lamb with any Wensleydale mate whatever. For the present the inconvenience of breeding tests must be faced unless the production of guaranteed rams is to be postponed for a very long time.

---

*This and other fundamental problems that present themselves in this Wensleydale work have been discussed in a recent review in this *Journal* (1925, **16**, P266).

18—THE DETECTION AND ESTIMATION OF GLYCEROL IN COTTON CLOTHS AND SIZED YARNS*

By George Smith, M.Sc., A.I.C.

Glycerol, in the form of various grades of commercial glycerine, is used to a considerable extent in both the sizing and finishing trades, and it is therefore surprising that the published schemes of chemical analysis of yarns and cloths in no case include reliable methods for either the qualitative detection or the estimation of this substance.

QUALITATIVE

Dannerth[1] states that glycerol in sized cloth may be detected by the production of acrolein when a concentrated aqueous extract of the cloth is heated with potassium hydrogen sulphate. This test is not sufficiently selective, nearly all sized cloths giving a positive reaction, whether containing glycerol or not. A preliminary investigation of a number of other tests for the identification of glycerol showed that the most suitable for the purpose in hand is the Schotten-Baumann method of benzoylation in aqueous solution, whereby is obtained a crystalline glyceryl dibenzoate, m.p. 72–73° C.[2] The reaction, crystallisation of the product from alcohol, and determination of the melting point, can be carried out easily, using 0·05 gram of glycerol in dilute solution. A method has therefore been devised for obtaining from cloth or yarn an extract containing the glycerol sufficiently free from other constituents of the size and of the cotton to allow benzoylation to proceed normally. The only other method of testing for glycerol which has given satisfactory results when applied to sized cottons is that of Denigés,[3] depending on the oxidation of glycerol, in aqueous solution, to dihydroxyacetone, and the production of distinctively coloured bodies when this is condensed with phenolic substances in the presence of concentrated sulphuric acid.

The Benzoylation Test

Method of Extraction—A suitable quantity of yarn or cloth—about 20 grams of a pure-sized cloth—is extracted for three hours in a Soxhlet apparatus with 95% alcohol. The extract may contain, in addition to glycerol, zinc and magnesium salts, soap and fatty acids from the size, and waxy matter, together with substances not yet identified, from the cotton itself. Most of the wax separates on cooling the alcoholic solution, and may be filtered off. In the case of a more heavily sized cloth, where glycerol, if present at all, will occur in comparatively large amount, a much smaller quantity of the sample is extracted, usually 5–10 grams, and the amount of wax obtained in the alcoholic extract is so small that filtration at this point may be omitted. The alcoholic solution is evaporated on the water-bath to about 2 cc. and is then shaken with 20 cc. of warm, very dilute hydrochloric acid. The cooled mixture is filtered, or extracted with ether, to remove all fatty matter, and is next boiled with a very slight excess of sodium carbonate in order to precipitate zinc. When all the liberated carbon dioxide has been driven off, a few drops of 10% caustic soda are added, to complete the precipitation of magnesium. The solution is filtered, carefully neutralised with hydrochloric acid, and evaporated to approximately 5 cc. If zinc and magnesium are known to be absent, the solution, after removal of the fatty matter, may be neutralised with caustic soda and evaporated at once. The benzoylation reaction is carried out with this solution.

* This and the following paper were read at a meeting of the Lancashire Section of the Institute on 12th February. The discussion follows on pages T206-T212.

Benzoylation—The reaction is best performed with a considerable excess of benzoyl chloride. The glycerol extract is shaken with 1 cc. of benzoyl chloride and 5 cc. of 10% caustic soda solution, together with one drop of methyl red indicator solution. As soon as the precipitated glyceryl benzoate turns red more caustic soda is added, a few drops at a time, with vigorous shaking, until the odour of benzoyl chloride disappears. The somewhat oily product is filtered off, washed with water and then dissolved, without drying, by pouring 2 cc. of boiling alcohol through the filter, which should be very small. The alcoholic solution is allowed to crystallise slowly, preferably in a small test tube. At first some oily substance separates, apparently the benzoate of some unidentified constituent of cotton which is extracted by alcohol and is not removed by the method of purification described. If the crystallisation is allowed to proceed slowly, the whole of the oily substance separates first, and the glyceryl benzoate crystallises above it as clusters of fine needles which are readily separated from the viscous oil, and which, without further purification, have a sufficiently sharp melting point.

Experimental—The test, as described, has been performed on a number of typical yarns and cloths, of known composition, some of which, containing no glycerol, were used in order to find whether any interfering substance is likely to be present in cottons or in the more common sizing materials. For each of the samples containing glycerol the approximate percentage of the latter on the material, calculated from sizing data, is given.

SAMPLE No. 1—90's Egyptian yarn, pure size. The size contained glycerine, japan wax, spermaceti, starches, and zinc chloride. Amount of glycerol in yarn, approximately 0·3%; 20 grams of yarn was used for the test, carried out as described. Obtained pure white needles of the benzoate, m.p. 71–72° C.

SAMPLE No. 2—Tinted cloth, the warp sized to add 30% weight. The size contained glycerine, spermaceti, starches, china clay, magnesium sulphate, salicylic acid, and a small amount of direct cotton dyestuff. Approximate amount of glycerol in cloth, 0·8%. The test was performed with 10 grams of the sample. Obtained pure white needles, m.p. 71–72° C.

SAMPLE No. 3—Tinted cloth, the warp sized to add 100% weight. The size contained glycerine, wheaten flour, starch, china clay, magnesium sulphate, zinc chloride, and direct cotton dyestuff. Amount of glycerol in cloth approximately 2%. 7 grams of cloth was used for the test. Obtained an abundant crop of benzoate crystals, m.p. 71–71·5° C.

SAMPLE No. 4—Plain cloth made from very coarse American yarns. The size contained the same ingredients as No. 1. The amount of glycerol in the cloth was 0·1%. 50 grams of cloth was used for the test. The purified extract was very dark coloured, but on benzoylation gave a pure white product, m.p. 70–72° C.

SAMPLE No. 5—44's American yarn, sized to add 50% weight. The size contained tallow, wheaten flour, starch, china clay, magnesium chloride, zinc chloride, and dyestuff. It contained no glycerol. 25 grams of the sample was taken for the test. Benzoylation gave only a small quantity of oily and uncrystallisable product.

SAMPLE No. 6—90's Egyptian yarn, pure size. The size contained fats, starches, and zinc chloride. It contained no glycerol. 20 grams of yarn gave a small amount of oily benzoate, which could not be crystallised.

Colour Reactions

Since Denigés' publication[3] is not readily obtainable in this country, the method of carrying out the tests is given here.

> 0·1 gram of glycerol (in dilute solution if necessary) is heated on the water-bath with 10 cc. of a 0·3% solution of bromine for 20 minutes. If, at the end of that time, it is still coloured, the solution is heated further, with constant shaking, until the yellow colour of the bromine has entirely disappeared. This solution is subsequently designated "Solution G." If the amount of glycerol available is less than 0·1 gram, the same quantity of bromine is still used. "Solution G" may, if desired, be concentrated to one-tenth its volume in order to render the reactions more distinct.
>
> "Solution G" gives the following reactions. All the phenolic bodies are used in 5% alcoholic solution.

Solution G	Phenolic Body	Sulphuric Acid (strong)	Method	Result
0·2 cc.	0·1 cc. Codeine ...	2 cc.	Heat on water bath for 2 minutes	Clear greenish-blue
0·4 cc.	0·1 cc. β-Naphthol ...	2 cc.	,,	Emerald green solution with strong green fluoresence
0·4 cc.	0·1 cc. of 4% potassium bromide and 0·1 cc. salicylic acid *	2 cc.	,,	Violet or wine red colour
0·4 cc.	0·1 cc. Thymol ...	2 cc.	In the cold	Pale rose to blood red
0·4 cc.	0·1 cc. Resorcinol ...	2 cc.	,,	Yellow to orange

*A drop of methyl salicylate used instead, gives, in the cold, intense violet colour, while guiacol gives a blue-violet colour.

R. Delaby[4] states that only one of the colour reactions, that with codeine, is specific for glycerol, all the other reactions being given by glycerol homologues.

Experimental—A number of yarns and cloths were tested in order to find whether the above reactions are applicable to the characterisation of glycerol in size. 5–10 grams of yarn or cloth was extracted with 95% alcohol in a Soxhlet. The alcoholic extract was evaporated nearly to dryness, the residue warmed with a few cc. of very dilute acid, filtered, and evaporated to about 1 cc. The oxidation with bromine was performed on this solution. In cases where the concentrated alcoholic extract was very dark coloured it was evaporated with a little hydrochloric acid till syrupy. Some charring of organic matter took place, and on addition of water and filtration, a clear solution, only slightly coloured, was obtained. In all cases the volume of "Solution G" was adjusted to about 5 cc.

Sample No. 7—Yarn, sized for weaving only, containing approximately 0·5% glycerol. The correct colours were obtained with thymol, codeine, β-naphthol, salicylic acid, and salicylates. Resorcinol was not used, since a distinct brownish-yellow colour was obtained in the absence of any phenol.

It was found that phenyl salicylate, in 5% alcoholic solution, gives a better reaction than either the free acid or the alkyl salicylates.

Sample No. 8—Cloth, heavily sized, containing 2·5% glycerol. The correct colours were obtained with all the reagents.

Sample No. 9—Cloth, heavily sized, containing no glycerol. Phenyl salicylate gave a very pale reddish colour. Codeine gave no colouration. Thymol gave an orange-red colour. β-Naphthol gave a deep fluorescent green. Repeat tests on this cloth gave always the same result. Thymol and β-naphthol were therefore not used for further tests, and codeine and phenyl salicylate alone retained.

Sample No. 10—Cloth containing approximately 1·5% glycerol, sized medium weight. Phenyl salicylate gave an intense violet colour, codeine pure greenish-blue.

Sample No. 11—Cloth containing 0·2% glycerol, pure size. Phenyl salicylate gave a strong purple colour, codeine gave pale brown. Several repeat tests with this cloth gave invariably a strong positive reaction with phenyl salicylate, but no blue colour with codeine.

Conclusions—Of the colour reactions described by Denigès, only the ones with codeine and with phenyl salicylate are sufficiently specific for the detection of glycerol in sized cloth. Phenyl salicylate gives the more distinctive reaction, the colour being very intense and not readily masked. The greenish-blue colour given by codeine is very easily masked by a trace of brown, and the test is nullified in this way if "Solution G" contains a trace of organic matter which is charred by sulphuric acid.

QUANTITATIVE

An attempt has been made to estimate small quantities of glycerol in cotton goods by the "I.S.M." acetin process,[5] the glycerol being extracted from the cloth and freed, as far as possible, from substances likely to interfere, exactly as described above under "Benzoylation Test."

The work was undertaken originally in order to find a means of estimating glycerol in comparatively heavily sized cloths, containing from 1% to 3% of glycerol. The method tried and here described will estimate glycerol in such cases with fair accuracy. Attempts to adapt the method to the analysis of lightly sized cloths, containing from 0·1% to 0·5% glycerol, have not been successful, the amount of glycerol found being always much too high. This is attributed to the presence, in the final glycerol extract, of the substance which has been noted above to form an oily benzoate, and which, as may be expected, acetylates along with the glycerol. If a sample of the particular unsized yarn is available, this difficulty may, of course, be obviated by means of a "blank."

Apart from this, however, it is considered that the acetin method is unsuitable for the estimation of glycerol in such small amount. The final titration is performed in a large volume of solution containing a considerable quantity of sodium acetate, and the end-point is not sufficiently sharp to ensure accuracy. Throughout the work the amounts of acetic anhydride and fused sodium acetate used have been those recommended in the "standard method." It was not considered advisable to reduce these, in spite of the very small quantity of glycerol present in an estimation, since it is difficult to free the extracted glycerol from water without losing glycerol by over-evaporation.

Experimental

A number of cloths, sized with known mixtures, were used to test the method. In each case the total amount of size on the cloth was determined experimentally, using a modification of the method described by Bean.[6] The percentage of glycerol in the cloth was then calculated from the known composition of the size. The figures thus obtained are necessarily approximate only, since average figures have had to be used in allowing for differences in moisture content of sizing ingredients in the raw state and on the cloth.

As stated above, the glycerol was extracted from the cloth and purified as described under the benzoylation test. The final neutralised solution thus obtained was evaporated *in vacuo* on the water-bath until practically all the salt had separated out and the crystalline mass remained only just moist. Particular care had to be taken not to carry the evaporation to absolute dryness. This final evaporation was carried out in the flask in which the acetylation was to be performed. In a few early experiments the glycerol was separated from the salt residue by washing several times with a mixture of alcohol and ether. This was found to be unnecessary, having no effect on the amount of glycerol found. The results of a number of typical estimations are given in Table I.

Table I.

Sample	Amount of Size on sample	Wt. of Sample analysed	Amount of Glycerol on sample: Calculated	Found
Cloth A	38·5%	8·5 grams	2·75%	2·71%, 2·64%
Cloth B	11·6%	15 ,,	0·90%	0·98%, 0·98%, 0·99%
Cloth C	18·7%	15 ,,	1·58%	1·63%, 1·65%, 1·65%
Cloth D	33·2%	7 to 8 ,,	2·38%	2·42%, 2·34%, 2·41%, 2·43%, 2·38%
Cloth E	5·1%	40 ,,	0·20%	0·29%
Yarn A1	10·2%	20 ,,	0·40%	0·49%, 0·49%, 0·48%, 0·49%
Yarn E1	16·0%	35 ,,	0·31%	0·41%
Some unsized American yarns	...	...	...	0·13%, 0·15%, 0·06%, 0·12%

SUMMARY AND CONCLUSION

(1) Glycerol in sized cloth or yarn may be detected by suitable purification of an alcoholic extract of the sample and characterisation of the glycerol by the formation of a crystalline glyceryl benzoate, m.p. 72–73° C.

(2) A further method of identification of glycerol is by means of certain of Denigés' colour reactions.

(3) The "I.S.M." acetin method may be used to estimate glycerol in cotton goods, with fair accuracy, if the amount present exceeds 1% of the weight of the sample, but the method is not suitable for the estimation of glycerol in pure-sized goods, where the percentage is much less than 1%.

The author's thanks are due to Messrs. Boardman & Baron, Ltd., of Great Harwood, in whose laboratory the work was carried out, for permission to publish the results of this investigation.

19—THE EFFECT OF SIZES ON THE ELASTIC BEHAVIOUR OF FLAX YARNS*

By J. A. Matthew, M.Sc.(Lond.), A.R.C.S., F.Inst.P.
(York Street Flax Spinning Co. Ltd.)

PART I.

INTRODUCTION

An investigation has been carried out on the effect of various sizing ingredients on flax yarns used as warps in weaving. The primary object was to obtain a quantitative estimate of the effect of various sizes and ingredients on the elastic behaviour of the yarn, but at the same time some attention was paid to the resistance to rubbing of the sized yarns.

In preparing warp yarns for the loom, they go through the processes of winding and beaming, and then dressing, which briefly comprises the passage of the yarn through a size trough, drying by passage over a hot air chamber, and when dry, winding on to the weavers' beam. Tallow is sometimes applied to the dried yarn. The object of the applied dressing or size is stated to be to lay the hair or loose fibres on the surface of the yarn, thus reducing friction in the shedding and facilitating the weaving operations. That is, the sized yarn should have a smooth surface able to resist the friction experienced at various places during its passage through the loom.

It appears to be generally recognised that the addition of the usual sizing mixtures reduces the elasticity of the yarn, at the same time increasing the breaking strength. There appear, however, to be very few data published on the quantitative effect of the size in reducing the elasticity. The experiments to be described were undertaken in order to study sizes and sizing materials as an aid to weaving efficiency alone. The question of the use of sizes in order to produce certain finishes involves entirely different conditions.

CONSIDERATION OF FACTORS DEFINING WEAVING EFFICIENCY

A good-weaving warp yarn may be defined as one which will pass through the loom without breaking or being unduly weakened, and without presenting a frayed appearance, as this would militate against a good finish in the completed fabric. Three physical factors are usually mentioned in connection with the effects of sizes, and these are—

(*a*) Weight of size on the yarn.
(*b*) Strength of the sized yarn.
(*c*) Elasticity of the yarn.

In connection with this investigation, the *weight of size* did not appear to be very important; the view taken was that so long as the size was evenly applied and not excessive in quantity, the exact amount was immaterial so long as it enabled the yarn to withstand the friction on the loom.

* This and the foregoing paper, No. 18, were read at a meeting of the Lancashire Section of the Institute on 12th February. The discussion following the reading of these papers appears on pages T206-T212.

The *breaking strength* is undoubtedly an important factor and one which is well recognised. The effect of the usually employed size mixtures is to increase the breaking strength. Since the friction on the loom is, in the case of maximum efficiency, to be entirely absorbed by the dressing, it should be possible for the yarn itself to go through the weaving process without loss in strength. That is, if the yarn after passage through the loom was desized and tested, its strength should be the same as before sizing. If, however, the sized yarn were tested after emerging from the loom, its strength would show a decrease,[1] but unless this strength is less than that of the yarn before sizing, it need not necessarily follow that this yarn if desized would be weaker than before sizing.

The *elasticity* of the yarn must be an extremely important factor in weaving, where the applied stresses are varying so rapidly. The term elasticity is very often erroneously used to mean the elongation at break, whereas its real meaning, applicable as long as Hook's Law is obeyed, is the amount of stress per unit strain, where the strain is the actual stretch divided by the original length. When samples are tested in comparison, the samples being of the same weight per unit length, and the same length, this definition of elasticity becomes equal to the applied load required to produce unit stretch. That is, it is a measure of the rate of stretching with load. It is therefore necessary to consider the behaviour of the yarn at all stages during the application of the load, and in these experiments this has been done, in addition to noting the more usually measured elongation at break.

In order to be able to compare quantitatively the probable behaviour of various yarns, a single figure is required which takes into account variations in strength and elasticity, as both must be taken into account. Now it has been found in all cases of sized, boiled, flax yarns, that the relation between load and stretch is almost exactly represented by a straight line. Consider the cases represented in Diagram 1. The lines OA and OB show how the yarns A and B stretch according to the amount of load applied, and mean that B stretches more easily than A. If both have the same breaking strength OX_0, then BX_0 and AX_0 represent the elongations at break of B and A respectively, and so in this case the elongation at break would serve as a measure of the elasticity of the yarn, but this is only true when the breaking strengths are equal. For example, if yarn A had a breaking strength OX_1, then the elongation at break would be $A_1X_1 = BX_0$, and in this case the elongation at break would not serve to differentiate between A and B as regards elasticity. Also we see from this diagram that when the elasticity is constant for different samples, then the elongation at break and breaking strength are proportional. From such a diagram, however, a figure combining varying elasticity and breaking strength can be evaluated, which is the *work to break*, or the amount of energy which must be expended to break the yarn. Consider Diagram 2. The lines OA and OB represent the stretch at every stage of applying load up to the breaking point, as before. The area OBD represents the sum of the products of load by extension at every stage, and is therefore a measure of the work done up to the breaking point. In the cases of sized flax yarns OA and OB are practically straight lines, so the areas can be calculated from the product of half the breaking load $\times$ elongation at break. In the case of an unsized yarn, the area becomes similar to OCF, which cannot be so simply calculated, but the area can be measured by means of a planimeter. This *work to break* therefore now allows of a comparison

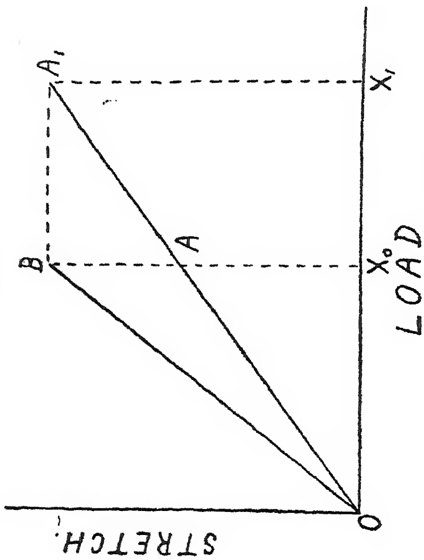

DIAGRAM 1

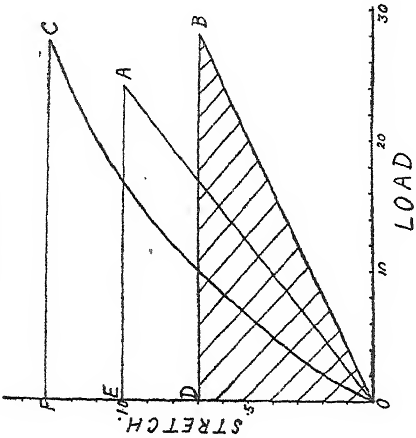

DIAGRAM 2

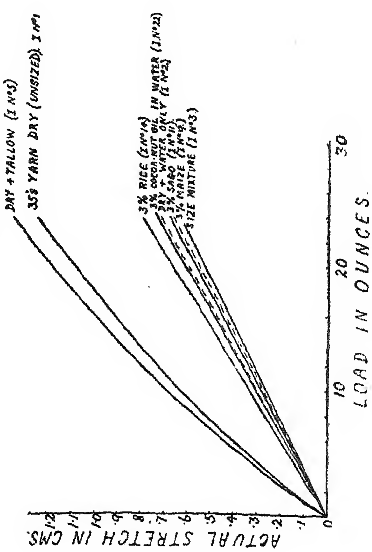

DIAGRAM 3

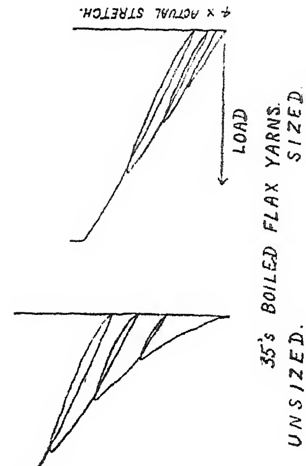

DIAGRAM 4

between samples of different strengths and elasticities. Thus, yarn A is weaker than B, but it stretches more readily or is more elastic than B. Calculating the respective works to break we get—

Work to Break

$$A = \tfrac{1}{2}\ AE \times OE = \tfrac{1}{2}\ 24 \times 10 = 120$$
$$B = \tfrac{1}{2}\ BD \times OD = \tfrac{1}{2}\ 29 \times 7 = 101{\cdot}5$$

from which it would be concluded that yarn A would give the better result in working, although B has the greater breaking strength. This clearly shows the advantage of increasing the elasticity so far as efficiency of working of yarn in weaving is concerned. To sum up this theoretical survey of the conditions affecting the efficiency in weaving of sized yarns, it may be concluded that—

(1) The function of the size is to give the yarn a smooth surface which enables it to pass over the loom without loss in strength or presenting a frayed appearance.

(2) Whilst measurements of breaking strength or elongation at break may be helpful in considering the behaviour of the yarn under working conditions, they do not alone suffice.

(3) A measurement of the work to break gives an indication of the behaviour of the yarn under working conditions, as it combines the effects of strength and elasticity. This necessitates a knowledge of the behaviour of the yarn in stretching under loads at all stages up to the breaking point.

(4) The importance of having the elasticity as great as possible is indicated.

EXPERIMENTAL

In making a study of the efficiency in weaving of sized warp yarns, it appeared desirable to determine the elastic behaviour of yarns dressed with ordinary mixtures, and also with a variety of ingredients alone, with the ultimate object of preparing mixtures which would give the maximum possible elasticity to the sized yarns compatible with sufficient strength and resistance to friction. Dressings were prepared in the laboratory and applied in the usual way on the dressing machine, the felt covers on the roller being carefully cleaned between each sample. Only a few strands were sized at a time, and only enough prepared for the necessary tests to be made. In this way a small stock of yarn originally wound on to a number of spools sufficed for the whole investigation; the same yarn then was used throughout, and being fairly small in quantity, variations in the quality of the yarn were eliminated as far as possible. The dressings were prepared in various groups, such as starches, softeners, &c., about eight samples to each group. In this way direct comparison could be obtained between the effects of the members of each group, atmospheric effects on the test results being eliminated as far as possible by conditioning together and testing in rotation.

With every set of dressings tested, a sample of the undressed yarn was put through the dressing machine, exactly in the same way but with the size trough empty. The object of this was to give the undressed yarn the same tension effects, and by using this sample as a control for the set, the effect of the addition of the size alone should be obtained. The results are tabulated, but in order that samples in one set may be directly compared with samples in any other set, prepared and tested at different times, the actual results are not quoted, but the results expressed as a percentage of those of the control for the set.

All samples were allowed to condition for one week in the laboratory before testing, and records were made of the lea, breaking strength, elasticity, the appearance and feel, and the resistance to rubbing. The *breaking strength* was determined on a Mulholland Yarn Tester, 100 breaks being taken in each case. The *elasticity* measurements were made on the machine already described by the author.[2]

The yarn employed was a 35's boiled yarn of very good quality.

In this investigation the following procedure was adopted. The rate of loading was kept constant at 22 ounces per minute throughout; this rate is quite slow compared with actual working conditions, but faster than previously employed. A slow rate of loading is beneficial in testing, as it is found that very consistent results can be obtained from a small number of tests.

Twelve lengths (30 inches) of each sample were tested, and an autographic record obtained of the load-stretch diagram. Each drum chart allowed room for three diagrams, so three tests were made of each sample in rotation, and all sequences were completed when once started. From these curves, the elongation at break and breaking strength were noted, and by averaging the various loads at certain extensions, a mean load-stretch diagram for the sample was constructed. These mean curves can then be plotted on the same diagram for comparison, but for purposes of tabulation, the elongation at some arbitrarily selected load was noted. Since the test length remains constant and the lea of the yarn is also constant, except for small variations due to varying amounts of size taken up, this figure serves as a convenient measure of the rate of stretching of the yarns under these conditions. This load was fixed at 20 ounces, being about two-thirds of the mean breaking strength, and so allowing a good margin for variation in strength of the various samples.

In addition, some further tests, three on each sample, were made in which the yarns were alternately loaded and unloaded as described in the previous paper,[2] from which mean values were determined of the ratio of Total/Permanent stretch, and hence of the percentage of elastic in the total stretch.

The *resistance to friction* was tested in a qualitative manner, on a small machine designed for the purpose. A qualitative test, that is, one in which the yarn is subjected to a fixed amount of rubbing, and its appearance examined visually, appeared on consideration to be all that was necessary for the purposes of this investigation. It has the advantage that when once the desirable amount of rubbing has been determined, samples can be tested in a short time. There are two methods of making a rubbing test quantitative—

(1) To count the number of rubs before break occurs;
(2) To subject the yarn to a fixed number of rubs; and to determine the loss in breaking strength.

Such tests necessitate a more complicated machine and involve much more time. In the first case, it gives no information on the appearance of the yarn after rubbing, which, as was pointed out in an earlier section, is probably one of the most important and desirable features in a size; in connection with the second case, it has been pointed out that strength tests on sized yarns after rubbing do not necessarily give an indication of the effect of rubbing on the strength of the yarn itself.

The machine used was fitted up to attempt to produce in a small way the rubbing to which yarn is subjected in weaving. The actual conditions

can, of course, only be obtained in a loom, but for experimental purposes where comparative work only is in question, the actual conditions are not so important, so long as they are sufficiently severe to produce a good fraying effect on an unsized yarn and leave sufficient range for judging the effects on various sizes.

The machine consisted of a bobbin containing the yarn, tension being applied by a leather brake acting on the rim of the bobbin, a rocking arm carrying a set of reed pins in a frame on the end, and a second bobbin for winding up the yarn. The rocking arm and take-up bobbin were geared together, and the whole machine driven by a belt from a shaft or electric motor, so that the speed of the yarn and the number of oscillations of the rocking arm represent those experienced in an average loom. Besides the friction between the reeds and the yarn, other rubbing surfaces were introduced, such as wooden bars to represent the lease rods, a piece of a heddle suspended from a spring and kept tight by a hanging weight, and a curved iron surface for the yarn to rub over in changing from the horizontal to the vertical before reaching the take-up bobbin. By suitably arranging the tension on the yarn, and the path through the machine, which chiefly affects the angle of the yarn around the reed pins, a large variation can be obtained in the amount of friction experienced by the yarn. The conditions were arranged by trial so that an unsized boiled yarn was considerably frayed, but a sized yarn, dressed with a mixture known to give satisfactory results in practice, showed little or no effect after rubbing. These conditions were then adopted as a standard for the series of tests to be made. Specimens of each sample, before and after rubbing, were then mounted side by side on a black card which renders visual examination of the appearance very easy.

The experiments were designed to cover the following main headings—

(i.) A compound size mixture and the effect of tallow.
(ii.) Various starches and varying strengths of paste.
(iii.) Gums in equal strength solutions.
(iv.) Softeners (including deliquescents) as solutions or emulsions in water, of constant strength.

The effect of friction was only tested on the samples under the first three heads. The results are tabulated in Table I. and some results are shown graphically and will be referred to in detail later.

Discussion of the Results in Table I.

Appearance and the Resistance to Rubbing—In this series the Size Mixture No. 3 was regarded as a standard, as it was known to give satisfactory results on a loom. It appears that water alone adds slightly to the resisting power as it causes a hardening of the yarn, but the chief factor in causing resistance to rubbing is the sizing material added. If these results may be taken as truly representative, it would appear that tallow added as an external layer reduces the effect of rubbing on an unsized yarn (No. 5), but slightly increases this effect on a sized yarn (No. 4). A possible explanation may be that the tallow softens the size layer and so allows abrasion to take place more easily.

Of the various starches, the appearance before rubbing appeared to be best with maize, with sago, potato, and rice next in order. Varying the strength of the paste made no striking differences. The resistance to rubbing appeared also to be in the same order, with rice distinctly the worst. There was an indication that increasing the strength of the paste increased the power of resistance to the rubbing.

20	2% Quellin (soluble starch)	121·6	65·8	80·0	45·5	4·75	78·9	—	Slightly firmer, but still hairy ...	Some fraying.
21	2% Irish moss	118	66·9	78·9	44·5	4·66	78·4	—	Fibre well laid, firm, and springy	Frayed more than No. 20.
	IV.—*Softeners and Deliquescents in Water*									
22	3% Cocoanut oil emulsion	101·8	66·6	67·8	56·3	2·5	60	—		
23	3% Tallow emulsion	111	65·9	73·1	51·2	4·24	76·5	—		
24	3% Hardened whale oil emulsion	111	70·6	78·4	55·0	4·49	77·9	—		
25	3% Oleine oil solution	97·4	61·2	59·6	54·7	5·28	61·2	—		
26	1% Soap solution	103·4	57·1	59·0	47·5	3·23	69	—		
27	3% Glycerine solution	115·4	65·3	75·3	49·5	4·08	75·4	—		
28	3% Calcium chloride solution	110·2	67·7	74·6	53·8	4·08	75·4	—		

In Section III., gum tragon gave a very good appearance and a total resistance to rubbing, and therefore appears as good as maize starch, although in much weaker solution. A deciding factor, if other considerations such as strength and elasticity were also equal, would be the relative cost of these two materials. Irish moss gave a yarn of very good appearance, but the resistance to rubbing was very poor. The other materials used in this section all gave poor results, both as to initial and final appearance.

An estimate of the *amount of size* taken up by the yarn is given in Column 9. The measurements were made on about 50-yard samples, and generally appear to be concordant, except in Nos. 8 and 9, which may be explained as due to yarn variation, but more probably, since the yarn was of good quality, may be due either to an anomalous behaviour of the rollers on the dressing machine or to some effect connected with the extremely high viscosity of such pastes as 5% potato and maize starches. Comparison of Nos. 3, 4, and 5 show that a sized yarn only takes up about half as much tallow, applied from a brush, as an unsized yarn; this is probably a penetration effect. In the cases of sago and rice, the amounts of size taken up are in the same order as the strengths of the paste. Repeat experiments with 3% sago (Nos. 11 and 15) gave very similar figures.

The *breaking strengths* are given in Column 3. Only in two cases (Nos. 19 and 25) were the treated yarns weaker than the dry yarn; Nos. 22 and 26, both softeners, gave only slight increases, whilst the remainder were all decidedly stronger than the dry yarn, with the Size Mixture No. 3 giving the strongest yarn. Except for the four samples first mentioned, the strengths show only slight differences from that of the yarn treated with cold water alone. The addition of tallow to the Size Mixture No. 3 appears to cause a decided reduction in strength.

The *elasticity* is recorded in several ways, as follows—

(*a*) *Load Stretch Diagram*—The mean load stretch diagram for the dry (unsized yarn) is, as shown in Diagram 3, distinctly curved. Except for No. 5, the dry yarn treated with tallow, all the other tests recorded in Table I. gave graphs which were indistinguishable from straight lines, and a number of typical cases are also shown on this diagram. For this reason the values quoted in Column 6 for the elongation at 20 ounces load give a strict comparison of the rate of stretching of the yarns under these conditions of loading. It will be seen that, considering the wide variety of materials used, there is a surprisingly small variation in the rate of stretching of the treated yarns, the extreme values being 44·6–61·3, with the majority between 50–55, and cold water only giving a value of 54·8. These results show therefore that in all these cases the rate of stretching of the sized yarns is only about one-half of that of the unsized yarn.

(*b*) *Per Cent. Elongation at Break*—These figures again show only a small range of variation for all the materials tested, which, of course, follows from the results mentioned above, because both the breaking strengths and rate of stretching have been seen to be fairly uniform.

(*c*) *Work to Break*—These figures are deduced from the area on the load stretch diagrams included between the graph and the ordinate or elongation scale, as mentioned in an earlier section. The values for the dry yarns (Nos. 1 and 5) were obtained with a planimeter, but in the other cases, since they gave practically straight lines, the values were calculated from half the product of breaking strength and elongation at break. Here again

the variation is not striking, and in every case the work to break is less for the sized yarns than for the dry yarn (unsized), No. 1. The Size Mixture No. 3, without tallow, gives decidedly the highest value, because of its outstanding breaking strength, but most of the starches and other adhesives gave values almost identical with the dry yarn treated with water only (No. 2). Several of the softeners also gave values as high as the starches and water, but oleine oil and soap solutions gave low values because of the low breaking strengths in these cases.

(*d*) *Ratio of Total/Permanent Stretch*—A very pronounced difference is shown between a sized and an unsized yarn, for which typical loading and unloading curves are shown in Diagram 4. The value of the ratio obtained from sized yarns is very high, and it is obvious from the diagrams that this is due to the comparatively small amount of permanent stretch obtained on unloading a sized yarn. Here again, however, only a comparatively small difference is obtained between the majority of the sizes tested, compared with the difference between sized and unsized yarns. The tallow added to the dry yarn (No. 5) gives rather a lower figure than the dry yarn, whilst cold water only gave a value about mid-way between those for the dry yarn and the majority of the other sized yarns.

(*e*) *The Per Cent. of Elastic in Total Stretch* is given in Column 8, and is obtained from the values in Column 7 as explained in the previous paper.[2] It will be seen that, as a consequence of the high ratio of total/permanent stretch, a sized yarn gives a much greater amount of recoverable stretch than an unsized yarn or an unsized yarn treated with tallow, but the interesting point again is that the actual difference in amount does not appear to be very greatly affected by the nature of the sizing material.

CONCLUSIONS

From the results of the tests recorded in Table I., the following conclusions may be made—

(1) The nature of the sizing material considerably affects the appearance of the yarn, and the materials differ considerably in their power of resisting rubbing, such as is experienced on a loom.

(2) The elastic behaviour of a sized yarn differs considerably from that of an unsized yarn, the load stretch curve is different in type, and the rate of stretching is very different. The nature of the loading and unloading diagrams also differ considerably, leading to a much higher value for the ratio of total/permanent stretch and of the per cent. of elastic in the total stretch for sized yarns, compared with unsized yarns.

(3) The elastic behaviour of a dry yarn treated with tallow alone from an ordinary tallow brush is similar in characteristics and amounts to the dry yarn.

(4) With small exceptions, no essential difference is found in strength and elastic behaviour between a yarn sized with a very wide range of materials including various starches, other adhesives and softeners and deliquescents applied with water, and water only.

The combined effects of conclusions (3) and (4) are of particular interest in connection with the objects of this investigation, showing briefly that the nature of the sizing material added to water, whether starch, gum, or softener, does not essentially and only in a slight manner, quantitatively, alter the effects of treating a yarn with water alone, as regards the strength and elasticity.

The original object of the investigation has therefore been answered, but not in the manner anticipated, as it is shown that no really significant alteration in the elastic behaviour and therefore in the efficiency of the sized yarn on the loom can be expected by any variation in the nature or proportion of the ingredients of the size; alteration of the size mixture, however, may be expected to affect the other essential of a size, namely, the resistance to rubbing.

PART II.

In the above it was shown that the elasticity of a boiled flax yarn is reduced by approximately 50% by the usual method of sizing. Some further experiments were then carried out to determine the cause of this reduction, since it was conclusively shown not to be dependent on the nature of the size. The similarity of the results from the 28 tests recorded in Table I., excepting Nos. 1 and 5, appeared to indicate that a common influence was acting on the yarns in all cases. Consideration of the experimental conditions apparently limits this influence to one or both of two factors, namely—

(1) The presence of water as a main constituent (about 95%) of the size.

(2) Some condition experienced on the dressing machine, the most probable appearing to be the tension on the yarn. Evidence that the first factor is involved is obtained from the tests, Nos. 1, 7, and 25, in Table I. In No. 27, tallow was applied as an emulsion in water, and the resulting sized yarn had elastic properties similar to all the other sizes containing starch, &c.; in No. 7, tallow was applied neat and the treated yarn had elastic properties similar to that of the dry (unsized) yarn. The only difference then in the treatment of Nos. 7 and 27 was the presence of water in the dressing.

Evidence that the tension on the sized yarn on the dressing machine may be important is obtained from a consideration of the great difference in value of the ratio of total/permanent stretch of sized and unsized yarns. As mentioned above, it is obvious from the loading and unloading diagrams shown in Diagram 4 that the difference arises from the small permanent stretch shown on unloading the sized yarn, compared with that shown on unloading the unsized yarn. This small amount of permanent stretch may be due, either (1) to an adhesive action of the size preventing slipping of the fibres past one another and tightening up of the fibres on one another during the loading, which is assumed to be the cause of the permanent stretch in an unsized yarn, or (2) to a large amount of the permanent stretch of the unsized yarn having been brought about during the sizing operation, such as by tension on the sized yarn in its wet state, the subsequent drying of the sized yarn under tension preventing its recovery.

Owen, in a paper on "Some Physical Tests of Sized Yarns,"[3] from measurements of extensions produced on sized and unsized cotton yarns by oscillations of tensions, found striking qualitative differences in behaviour which were interpreted as indicating a cementing action of the size, and the apparent equality of different sizings were explained on the assumption that in all cases the cementing action was complete, or in the average nearly so. Owen, therefore, under entirely different experimental conditions, arrived at the same conclusion as was drawn in Part I. of this paper, and adopted the first of the above explanations. His experiments, however, were confined to the effect of various starches, and this explanation does not seem so probable from the results given in Table I. as the same effect as with starch

and other adhesives is also found with water only and with water mixed with softeners, such as cocoanut oil, tallow, glycerine, &c.; on drying of the yarn the cocoanut oil, tallow, &c., alone would be left, and these would possess no adhesive power. It appears therefore from the above more general investigation that explanation (1) is not likely to be the controlling factor, so we are left to conclude that explanation (2) is the more probable.

It was concluded therefore, from consideration of all the available data, that the factors which caused the reduction of elasticity of the sized yarns

11	Tallow, rubber stripper, same setting as No. 8, tension 3 oz.	90·5	73	66·0	87·8	2·16	53·7

were the presence of water as a main ingredient of the size and/or the tension applied to the yarn on the dressing machine. The data were not sufficient to decide whether either alone or both together were necessary to produce the effects, so further experiments were made to decide this point. The measurements were confined to those of strength and elasticity, and the results are given in Table II.

These experiments were carried out in the laboratory and the yarns were not treated on the dressing machine, as before. The yarns were passed through a trough containing the dressing and then slowly pulled through a clamp between two pads of rubber which served the purpose of removing excess material and applying tension to the yarn. The yarns were then wound into hanks and dried on a pole in the laboratory. The conditions were therefore somewhat different from those existing on the dressing machine, as there the tension was maintained whilst drying was carried out. In each series of samples, the pressure on the rubber pads was maintained constant, but it was found that the tension on the yarns differed

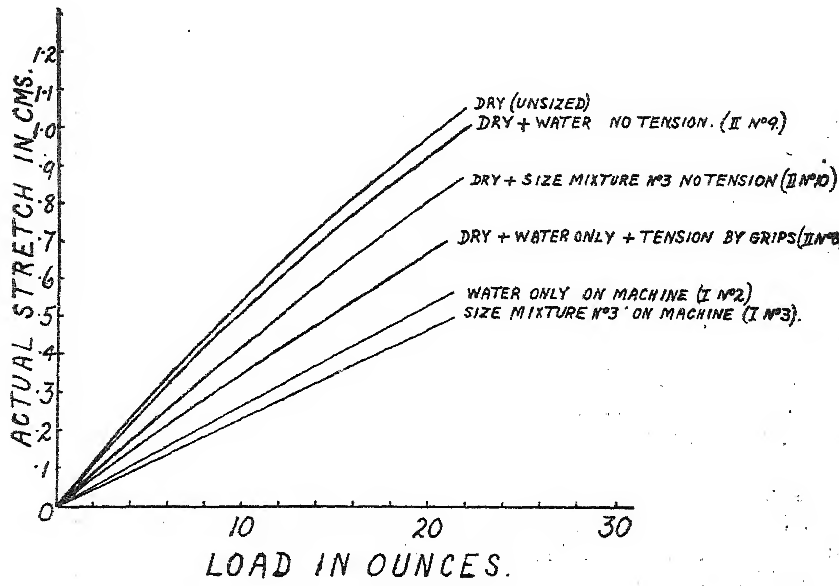

DIAGRAM 6

owing to the variation in lubricating power of the different materials. A dry (unsized) yarn was pulled through for comparison as before.

Tension in the Absence of Water

The first set of samples examined (Nos. 2–7) were treated with some of the softeners used in Table I. (also alcohol and trotter oil), but this time applied alone, so we get the condition of tension in the absence of water. It will be seen that glycerine (No. 5) slightly increases the strength and decidedly increases the rate of stretching, so the work to break is also markedly higher than that of the dry yarn. All the other samples showed a decrease in strength of varying amounts. The rate of stretching was greater than that of dry yarn in the cases of cocoanut oil (No. 2) and trotter oil (No. 6); hardened whale oil (No. 3), and tallow (No. 4) each showed a slight decrease. The work to break varied considerably according to the breaking strengths. The results for the ratio of total/permanent stretch in these cases were all very nearly equal to that of the dry yarn. The yarn treated with alcohol behaved quite differently from the others, showing a marked decrease in the rate of stretching, consequently a very low work to break, an approximately linear relation between stretch and load typical of ordinary sized yarns, and a ratio of total/permanent stretch considerably higher than that for the dry yarn.

The mean stretch-load diagrams are shown for these samples in Diagram 5. It is evident from these curves and the results mentioned, that in this set yarn treated with alcohol under tension has given results almost typical of an ordinary sized yarn, but in all the other cases, in which the dressings were applied under tension but in the absence of water, the elastic behaviour of the yarns are of the same type and quantitatively of the same order as for the dry unsized yarn. It appeared therefore that the presence of the water in sizes was necessary in order to produce the reduced elasticity found.

Tension in the Presence of Water

A further set of samples was prepared to determine the effect of tension in the presence of water. The mean load-stretch curves are shown in Diagram 6, with the addition of the curves for water only and Size Mixture No. 3 from Table I., to give a direct comparison with results from the dressing machine. In order to make Nos. 2–7 comparable with the behaviour of samples treated with water under the same conditions, one of them, tallow, was repeated, using the same conditions as for the water treated samples Nos. 8–10. Comparison of Nos. 4 and 11 therefore would indicate the relative applied tensions in the two experiments; the rate of stretching is lower in No. 11, and the ratio of total/permanent stretch is also a little higher, so it would appear that the tension on samples 8–11 was rather higher than in samples 2–7.

Comparison of No. 8, Table II., with No. 2, Table I., both for cold water alone, serves to connect the conditions in these experiments with those on the dressing machine. It will be seen that the results are very similar, the chief difference being in the rate of stretching. It would appear therefore that the laboratory conditions of applying these dressings produces results very similar to what would have been obtained on a dressing machine.

In No. 9 the yarn was soaked in cold water for a few minutes and dried on a pole, so no tension was applied. Comparison with No. 8 therefore shows the effect of tension only. The strengths of the two yarns were equal and greater than the dry yarn, but the yarn treated without tension gave results

for elasticity only very slightly less than those for the dry yarn, and consequently the work to break was very much higher than for dry yarn.

A similar test was made with the Size Mixture No. 3 of Table I., applying the size by soaking the yarn in the size and drying on a pole without tension. The strength was only very little higher than for the yarn treated with water only; the rate of stretching was decidedly lower than that of dry yarn, but the work to break still remained slightly greater than for dry yarn. The ratio of total/permanent stretch was slightly higher than that for dry yarn, but rather lower than for a pure tallow dressing applied under tension. Comparison of the figures for No. 10 in Table II. with those for No. 3 in Table I. shows the effect of tension only in the case of a size mixture, and it will be seen that the results of Nos. 8 and 9 with water only are fully confirmed.

Conclusions

It appears therefore from these results that tension must be applied to the water-treated yarn in order to produce the 50% reduction in elasticity found with ordinary sized yarns. The addition of water alone without tension produces a very slight reduction in elasticity, probably due to a binding action on the fibres; the addition of starch paste without tension gives a rather greater reducing effect on the elasticity than water alone, which probably indicates the true effect of adhesion due to the starch, but the behaviour is still typically the same as a dry (unsized) yarn. It is concluded therefore that the major cause of the small elasticity of sized flax yarns, compared with unsized, is the tension applied to the yarn on the dressing machine after wetting by the water in the size mixtures, only a relatively small effect being attributable to real adhesive effects of the starch or other adhesive ingredient.

The writer wishes to thank the Directors of the York Street Flax Spinning Co. Ltd. for permission to publish these results.

SUMMARY

As a result of an investigation of the sizing of flax warp yarns, including a large variety of the usual sizing ingredients, it is shown that the elasticity of a sized yarn is approximately only half of that of an unsized yarn, and that the behaviours on stretching are quite different, as is demonstrated by stretch-load diagrams. It is concluded that whilst the nature of the various ingredients will considerably affect the appearance of the yarn, both before and after weaving, owing to their differing in powers of resistance to rubbing, it will not essentially affect the strength and elastic behaviour of the sized yarn when applied in the usual way as a paste in water on a normal dressing machine, as practically the same result is given by treating with cold water only.

It is also shown that the major cause of this reduced elasticity of sized flax yarns is the tension applied to the yarn on the dressing machine after being wetted by the water in the size mixture, since the effect is not produced by tension in the absence of water, or by water in the absence of tension. A decrease in elasticity, due to real adhesive action of starch, is shown, but this is relatively small compared with the above.

Discussion

The Chairman, Mr. Peacy Bean, congratulated Mr. Smith on the patience he had shown and the work he had put into this paper. He said he was sure those present would regret that Mr. Smith had been unable to attend to read the paper himself and that everyone would be grateful to Mr. Farrow, of the British Cotton Industry Research Association, for reading the paper and for preparing the exhibit of solutions in demonstration of Mr. Smith's work. The use of glycerin in sizing had been known for many years, and thirty years ago he had used it, himself, fairly extensively in pure size mixings. Apart from pure sizing, however, there was no useful purpose to be served in employing it as a deliquescent, because the moment one introduced weighting materials in large quantities, such as China clay, Epsom salts, chloride of magnesium, and chloride of zinc, it became too expensive to use in anything like effective quantities. In heavy sizing there was nothing better than chloride of magnesium, which had the double advantage that it was a more powerful absorber of moisture than glycerin, and, at the same time, assisted materially in getting the required weight of size. It might be claimed that glycerin did not crystallise during very dry weather, especially when east winds were prevalent, and that chloride of magnesium did; but these conditions existed only during certain periods in the year. In any case, it was not possible to make size mixings to suit every possible condition, because the operation of sizing was usually conducted some time before the yarn got into the looms, and the yarn then had to remain for periods of from four to twelve weeks before the beams were woven out. In his opinion, apart from pure sized goods, which were intended for bleaching, or for pure sized goods intended for grey shipment, the use of glycerin in the size was an unnecessary expense. There was no material advantage in glycerin for heavy sized yarns which could not be got from chloride of magnesium at much less cost. Continuing, the Chairman pointed out that it had been stated in a text book on sizing that glycerin was more deliquescent than chloride of magnesium. This statement was not true, and it had led to the wasteful use of glycerin in heavy sizing. The author of the statement based his opinion on the result of an experiment in which he exposed glycerin at 52° Tw. and a solution of chloride of magnesium at 60° Tw. in the atmosphere. He found at the end of ten days that the glycerin had absorbed $8\frac{1}{2}\%$ of moisture, whereas the solution of chloride of magnesium had lost weight. Of course it would. The solution of chloride of magnesium already contained 70% of water, and would evaporate until a saturated solution would be formed, whereas glycerin at 52° Tw. was practically free from water. But on the yarn, chloride of magnesium is nearly dry, and in that condition it is capable of absorbing its own weight of moisture in a very short time.

Dr. W. H. Gibson remarked that it was very interesting to hear of such an apparently accurate method of determining glycerin. Could Mr. Farrow say whether it would work quite well with very crude glycerin containing the natural impurities?

Mr. F. D. Farrow said that this method of estimation of glycerol is only worked out in this particular case from the point of view of estimation of quite small quantities in yarns. Neither the qualitative nor the quantitative procedure described in the paper will enable any opinion to be given as to the quality of the glycerol used in size. The colour reactions do, however, permit as small a quantity as one milligramme of glycerol to be detected.

The Chairman remarked that if those engaged regularly in the analysis of cloth, for the purpose of matching size mixings, had to face complete quantitative determinations of glycerin, they would have a very unhappy time and so would the client when he got his bill. Apart from this, the paper was worth a considerable amount of study, but it was a chemist's paper and not for a cotton manufacturer. He then called upon Mr. J. A. Matthew to read his paper (No. 19 above), and asked him before reading the paper to outline the processes employed in sizing linen yarn, as there was a material difference between the processes employed in sizing cotton and linen yarns. Probably all those present knew something about the sizing of cotton yarns, and they might fall into the same error as he did when he read the paper, *i.e.*, reading about linen and thinking in terms of cotton. A brief outline was all that was necessary to enable them to make the necessary comparisons.

Mr. Matthew, before reading his paper, said that he was glad to comply with the Chairman's suggestion, and that in dressing flax yarns, they are first wound on the warper's beams, which are fed up in equal numbers at each end of the dressing machine. The yarns from these beams pass over a guide roller, between the nip of a heavily weighted flannel-covered pressing roller, and the size roller, the surface speed of which is the same as the speed of the yarn. This size roller revolves in the size trough, and so wets the yarn with size. After passing through the rollers, the yarns pass over the surface of a revolving brush, which removes excess of size, through a brass reed, and are then split into two layers by rods to facilitate drying, which is carried out by blowing hot air through the yarns by means of fans. The yarns then pass through a second brass reed, through the bristles of a tallow brush, under a guide roller, which directs them at right angles vertically upwards, through an ordinary "leasing heald" supported horizontally, and so on to the weaver's beam, where an expanding pressing roller rests on the yarns and so ensures a firm beam. The yarns are subjected to considerable tension during the whole time of their passage from the sizing roller to the beam.

The Chairman—The size is not boiling?

Mr. Matthew—No, it is cold. (Mr. Matthew then read an abstract of his paper illustrated by lantern slides.)

The Chairman said that they must congratulate Mr. Matthew on this paper. He had put an immense amount of work into it, and it contained a mass of detail. Whilst not wishing to be hypercritical he must say that the conclusions arrived at were those which applied also to cotton, and which had been known for many years. Much was made of the test for the breaking strength of sized yarns, but however valuable this test might be for unsized yarns, he failed to see what value it was in the case of the former. It was well known that if a yarn could be woven successfully for certain yarns with 10% of size, it did not necessarily improve the weaving qualities if 15% were incorporated; on the other hand, it might depreciate them. But this addition would materially increase the breaking strain. The most important weaving quality of a yarn was its pliability, and no machine had yet been invented which would measure the pliability, or the weaving quality, of a yarn, apart from the loom itself. In this paper nothing had been said about pliability, although, time after time, Mr. Matthew had been on the fringe of it. His experiments with water, his experiments with tallow, and other softening experiments, all seemed to indicate that he was

preparing to deal with this property of the yarn. Pliability was the main feature of a well-sized yarn, and an experienced tape sizer could tell, by feeling the yarn as it wound on the weaver's beam, whether it would be a good weaving yarn or not. It was not necessary for him to take short lengths of yarn and test them on a breaking machine, because his fingers told his brain whether the size was good enough. If during the operation of weaving sized warp, the yarn were subjected to a straight pull, the breaking strength test might be important. But in weaving, the yarn is not subjected to a straight pull, but to a bending action. This action might be compared to the bending of a piece of cardboard and a piece of tissue paper. It would not take many bendings to break the cardboard, but one might go on for ever bending the paper. If, however, the cardboard was subjected to a straight pull in a strength testing machine, it would beat the tissue paper out of the field. The pliability of a sized yarn is dependent upon the amount of moisture contained therein, and the amount of fatty matter. Moisture played a most important part, and he, the Chairman, would have liked the lecturer to say why more humidity was allowed in the weaving sheds in Ireland, where they were weaving linen, than is allowed in Lancashire, where they are weaving cotton. As a matter of fact, cotton is more hygroscopic than linen, and this has been allowed for in the regulations. Not only did moisture render the yarn more pliable, but it added considerably to its strength. On this account no strength tests were of value unless made under identical conditions of moisture and humidity of atmosphere. In these investigations much is made out of the "elasticity" of the yarn. He might be old fashioned, but it appeared to him that "elasticity" was something whereby anything which has been distorted had the power to return to its original shape. He could understand the "elasticity" of glass for instance, but he could not understand the confusion of "elasticity" with "stretch" as applied to yarn. The so-called "elasticity" of cotton or linen yarn depended upon several things, amongst which were the number of turns per inch, the evenness of the spinning, the amount of size, and the amount of moisture in the yarn. There was a good deal more in this matter of pliability than seemed to be thought by the younger investigators at the present time, and, in his opinion, many of the investigations were not being conducted on the right lines. It had probably dawned upon many of them that no machine, apart from the loom itself, was capable of testing the weaving qualities of a sized yarn, and until such time as they obtained a suitable machine they were wasting time in making innumerable strength and elasticity tests on sized yarn. One could get valuable information from such tests before the yarn was sized, but the introduction of size altered the conditions. It was suggested that investigators might be usefully employed in standardising size mixings. This was a hopeless task, and showed that those who suggested research on such lines had no knowledge of the practical side of the subject. There were such a variety of woven goods, made from such a variety of yarns, of such a variety of counts, of such a variety of qualities, that it would not be possible to standardise anything. Many weaving sheds were engaged, in normal times, on many varieties of goods, and the size had to be adapted for the particular goods. Then, again, a size mixing which would be successful in one mill might be altogether unsuitable in another because of the difference in conditions, differences too many to describe here. In the Burnley district there were a good many weaving sheds engaged on similar goods, known as Burnley printers.

In such a district one would think that a standard size mixing could be used, but experience had shown that it could not. After all, experience did count for something, even in these days of graphs and diagrams. There was one test, which might be described as the acid test, which should be applied to all these investigations and papers on sizing. How much are they going to increase production, and at the same time the weavers' wages ?

Many years ago he carried out experiments in sizing in conjunction with a friend who had the control of three weaving sheds, all situated in one mill yard. The same class of goods was woven in all three sheds. The size mixings were altered on definite lines after due consideration, and the results were watched. If the weavers' wages went down as a result of the change, it was concluded that the investigators were on wrong lines, but if they went up, then it was clear that they had made an improvement. Similar experiments were carried out with the object of ascertaining the antiseptic value of chloride of zinc, and the danger line was sometimes closely approached, but fortunately without the owners' knowledge. Some real practical information was secured. It has been said that the world was not given the benefit of these experiments, but this was not so. The facts were stated, but modern investigators demand graphs and diagrams. He was sure that Mr. Matthew would take his criticism in the best spirit; it was what is known as a Lancashire welcome. He uttered his criticism as a warning, because he knew that a tremendous amount of time had been spent, and was being spent, in regard to sizing which was wasted time, and which could be spent to much better advantage. Actually they had not a single new fact brought before them on the subject, in spite of the investigations going on all over the country.

Mr. F. D. Farrow said that Mr. Matthew had assumed that elasticity, *i.e.*, elongation, was an important factor in weaving. He did not know whether Mr. Matthew was right in that assumption or not, and he did not know on what grounds it was made; so far as he knew there was no evidence at all to show whether high breaking load was preferable to high elasticity. This paper was a very valuable examination of some of the physical properties of a warp yarn, but he thought it might have dealt with rather more radical variations of the sizing constituents. If Mr. Matthew pursued his experiments a little further he would probably find that important differences in the mechanical properties of the yarns were produced by varying methods of sizing. The word "pliability" had been used in the cotton trade for many years, without any very exact understanding of its meaning. He fancied Mr. Matthew's "elasticity" measured pliability as accurately as one could do it at the moment. He would respectfully suggest to the Council of the Institute that proofs of the papers be distributed before the meetings. Mr. Matthew had been at great pains to go into a lot of details which could have been omitted if copies of the paper had been supplied.

Dr. S. A. Shorter said that the autographic machine used by the lecturer was not a suitable one for investigating the elastic properties of yarns. It could not be used for recording the effect of very rapid extension and contraction. The actual records shown on the screen gave distinct evidence of errors due to friction and inertia. The question of recording rapid changes had been dealt with recently in the *Journal* of the Textile Institute, and a machine devised which is free from the defects of previous autographic recorders. The lecturer had shown very conclusively that the differences between elastic properties of the different samples had no relation to sizing,

but were due to the combined effects of tension and water. Did treatment with water alone improve the weaving properties?

The Chairman—No.

In that case, continued Dr. Shorter, all that the results showed was that the particular properties investigated were not involved in good or bad weaving, and had no very important bearing on the sizing problem. This effect of tension and water was fairly well known in colloid physics, and was common to all fibres. It was connected with the swelling process and was produced by other liquids which cause swelling. Alcohol is such a liquid and it was noteworthy that the effects obtained by the lecturer with water were also obtained with alcohol.

Mr. F. T. Peirce said the problems that arose in the linen and cotton industries were closely analogous in relation to weaving difficulties, the effects of tension, and of different sizes. There was, however, a fundamental difference, one of kind rather than degree, between flax and cotton yarns. One could easily see that the size penetrated more into cotton yarn and had a greater effect on its properties. Many of the statements made in the paper about flax were known experimentally not to be true of cotton. The cementing action played a bigger part and specific differences between sizes were much more marked, especially in their effect on extension. They had been given the results of an attempt to measure elasticity; this was a very important property but care was necessary in defining it. The figures given would be found to vary considerably with the rate of loading and the time allowed for recovery. In connection with the question of the effect of wetting alone, a big difference was shown in Table II. between the dry yarn and that soaked in water only. This could hardly be real; it must be due to the moisture conditions. Yarn that had been wetted retained more moisture than a dry yarn when the two are conditioned together.

Mr. H. J. S. Dewes suggested that a comparison could be made with a leather belt. If the individual fibres of a leather belt were lubricated with a suitable oil, the belt was made pliable and found to give much better service than one which was allowed to get hard and dry and not kept in a pliable state. He wondered whether a similar effect was not attained by the use of suitable softeners in the sizing process in ordinary mill practice in the weaving sheds of Lancashire to-day. After Mr. Bean's remarks about pliability of the cotton fibre he felt that this simile might be of interest.

The Chairman said that the main trouble with manufacturers and sizers was not that they had not got suitable sizing materials and did not know how to mix and use them, but to the fact that they did not know enough about the after processes to which the cloth was going to be subjected after it left their possession. A size mixing which would be quite suitable for goods intended for one purpose would be quite unsuitable for another. Without going into details, he would say that the most useful purpose served by an experienced chemist, as far as sizing was concerned, was in keeping manufacturers out of trouble, or helping them to minimise the trouble after they got into it. Manufacturers were like ordinary people—they consulted the lawyer when they had blundered instead of consulting him before they made the false step. But this sort of knowledge is open to anyone who reads the published works on the subject and has a knowledge of all sides of the trades connected with the production of cotton goods, from sizing to finishing. He mentioned the Burnley district in the early part of the discussion, saying that one might expect standard mixings in

their class of work. As a matter of fact the sizing of this class of goods was of the simplest, and few mixings could be improved upon if the best ingredients were employed. But here again they differ in different mills, due to differing conditions. In other districts, especially where heavy sizing is carried out or where coloured bordered goods are woven, standard mixings are impossible. He would suggest that there was room for research on the various starches. Everyone in the trade knows that for certain counts of yarn, and certain reeds and picks, the best starch to employ for the size is sago. Why is it that farina and tapioca lose strength when reboiled ? Why should maize starch have different characteristics altogether from wheaten starch ? They are all starches, and one would think that after they have been gelatinised by boiling, they would possess the same characteristics. Then, again, we had not got to the end of the possibilities in mercerising, and there was plenty of room for investigation in regard to cellulose and artificial silk. But in matters of sizing, bleaching, and finishing, there was little or no room for scientific research.

Mr. J. A. Matthew's reply (communicated)—As regards the point raised by the Chairman that differences of atmospheric moisture would affect the results obtained, as is fully described in the text, such a possibility was avoided as far as possible.

In reply to Mr. Farrow, it is agreed that the nature of the starch is of importance in regard to the resistance to rubbing, and it is only in regard to elasticity that the starches (when applied under identical conditions) appear to give the same result, and this was clearly indicated in the text of the paper.

I do not agree with Dr. Shorter that the type of machine employed would have any effect on the conclusions reached. A rapid rate of loading is not essential, and reliable inferences may be made so long as all the test conditions are kept the same for all the samples. This is also borne out from the similarity in the conclusions from these results and from Owen's, who used rapid oscillations of tensions.

The criticism of the next speaker, in regard to the ratio of total/permanent stretch, arose, I think, chiefly through my not having had time to deal fully with the details of the experimental conditions. With flax, further recovery on leaving the yarn unloaded would be small and very slow, but in order to eliminate any such effect from the measurements, reloading was always commenced with as little delay as possible. With more elastic yarns, such as cotton and wool, no doubt the "creeping" effect under stationary load would be proportionately more important, but with the results described, dealing with flax only, there is little reason to suppose that they are vitiated from this cause.

Communicated reply by Mr. G. Smith—

In reply to the Chairman, I may say that, at this juncture, I am not prepared to enter into a discussion *re* the relative merits of glycerol and magnesium chloride as deliquescents. Such a discussion would be entirely irrelevant to the subject of my paper. The fact remains, however, that glycerin *is* being used in sizing and, in my opinion, it is up to the analyst to be prepared to detect the presence of this substance in sized goods, and, if necessary, to estimate the amount.

A point not mentioned in the discussion is that the primary function of glycerin is to replace, not magnesium chloride, but fat. The result of a fat estimation therefore, provided the extraction is performed with petroleum ether or carbon tetrachloride and not with ordinary ether, is of the greatest value, to an analyst with a knowledge of sizing, in determining whether it in necessary to carry out specific tests for glycerol.

With reference to Dr. Gibson's question, several of the sized samples which I used in testing the methods contained crude glycerin, *i.e.*, 80% soap-makers' crude. I have detected no difference in behaviour between these samples and other samples sized with mixtures containing 98% distilled glycerin.

I would like to express here my thanks to Mr. Farrow for his presentation of my paper, and particularly for the experimental demonstration, which he himself suggested, of some of the reactions. G. SMITH.

20—A SIMPLE AND RELIABLE TEST FOR MERCERISATION

By R. W. Kinkead

(The Linen Industry Research Association)

The problem of distinguishing between mercerised and unmercerised material is frequently presented to the textile chemist. Methods at present available include microscopical examination and the use of Huebner's zinc chloride-iodine and aluminium chloride-iodine solutions,* which give a deep chocolate colour on mercerised material, unmercerised material remaining almost unchanged. E. Knecht† and A. B. Knaggs‡ suggest tinting cotton samples with Benzopurpurine 4B, when, on adding a little hydrochloric acid, the unmercerised sample turns blue while the mercerised sample becomes reddish-violet, provided too much acid has not been added. Similar differences are observed with linen materials provided mercerisation has been carried out very fully. The test, however, does not command confidence in general, because different materials require different quantities of acid to render the distinction evident. It appears impossible to find an acid solution of such a strength that it could be used as a general reagent. For instance, an acid solution which gives the reaction with a heavy closely woven damask in a satisfactory manner, is much too strong when testing an open woven cloth or a small cutting of yarn. Such a solution, with these materials, would turn both the mercerised and unmercerised samples a blue colour, while if the acid solution is sufficiently strong to turn the colour of the open-weave unmercerised cloth blue, and leave the mercerised cloth red, then both samples of the heavy damask remain entirely unchanged when treated with this solution. Moreover, the depth of shade produced on the material by the benzopurpurine is also a controlling factor, the deeper the colour the stronger is the acid solution required. This method therefore cannot be considered satisfactory, as in the absence of a similar piece of material known to be unmercerised, it does not give a definite indication. Microscopical examination is not a certain method of distinguishing mercerised from unmercerised material, and with the introduction of new finishing treatments is becoming more and more unreliable. Huebner's iodine methods have been found quite satisfactory with flax yarns. Difficulty is experienced, however, in applying the test to linen cloths. These will, in general, have been starched and finished, and the necessity for completely removing all traces of starch before the iodine test can be applied is a disadvantage where a rapid routine test is required. A very slight trace of starch will give with iodine the deep blue colour of iodo-starch which will mask entirely any colour difference between mercerised and unmercerised material.

The method now to be described resulted from a search for a reagent which would give an indication of mercerisation without necessitating comparison with a sample of similar material known to be unmercerised. The simplicity and, after a little experience, the certainty of the present test will commend it to those who have frequently to decide from the examination

*J.S.C.I., 1908, **27**, 105.
†J. Soc. Dyers and Col., 1908, **24**, 67.
‡J. Soc. Dyers and Col., 1908, **24**, 112.

of a small sample the treatment to which the material has been subjected.

The results described were obtained with a variety of linen cloths, damasks and yarns. Experiments have also been made with cotton, ramie, and hemp materials.

Method of Testing

A small cutting of the material is stained with Methylene Blue by soaking it for a few minutes in a cold approximately 0·001% solution of the dye, containing 0·5% of carbonate of soda. The stained material is rinsed with distilled water and covered in a test tube with about 10 cc. of a 3% sodium carbonate solution (approximately 6·5° Tw.). Four drops of iodine solution are then added. The iodine solution is made up by dissolving 1 gram iodine in 100 cc. of 20% potassium iodide solution. The test solution is heated rapidly to the boiling point, poured off, and immediately replaced by fresh cold carbonate solution. Under this treatment the coloration of mercerised material becomes reddish-purple, that of unmercerised material remaining blue, often with a greenish shade. The test has proved quite reliable for deciding whether or not a linen material has been given a normal mercerising process (*i.e.* treated with a caustic soda solution of a density not less than 40° Tw.). If an unmistakable purple colour is not obtained it may be concluded that the material has not been mercerised by a normal process. The effects of certain other treatments (*e.g.* the use of solutions of caustic soda of a density below 40° Tw. and the use of strong solutions of acids, &c.) are described below, but the indications given by the test in these cases are not regarded as perfectly definite.

Precautions

Prolonged heating of the stained material in the carbonate solution should be avoided as a considerable amount of the colour is thereby removed from the sample. In many cases, indeed, it will be seen that the colour change occurs on very slight warming, and when a qualitative test only is required, this is sufficient evidence of mercerisation. The pouring off and replacing of the first lot of carbonate is desirable because a considerable amount of colour is stripped from the material, making a blue solution, which may partially mask any colour change produced. Another advantage of this procedure is that the material is brought to room temperature very rapidly. A hot solution allowed to act for about a minute may bring about a slight colour change towards purple on unmercerised material, but the addition of cold soda restores the original blue colour. Similarly a sample which has been mercerised very slightly may assume quite a reddish-purple colour when hot, but becomes much bluer as the solution cools. The second solution should not be heated as almost any alkaline solution, however weak, will produce the colour change on unmercerised material if allowed to act for sufficient time at a high temperature. The shade of the unmercerised material is quite unaffected by the carbonate solution under the standard conditions of the test, as may be seen on comparison with a blank experiment in which the tinted material has been boiled in distilled water. After remaining in the cold carbonate solution for 3–4 hours, the shade of the unmercerised material will be only slightly changed. The difference between the colours of mercerised and unmercerised material is quite distinct after remaining in the carbonate solution for three days. The function of the iodine is to oxidise any reducing substances present in the

material which would reduce the Methylene Blue to the colourless leuco-compound. In alkaline solution Methylene Blue is easily reduced by the action of various compounds which may be present in the material to be tested. Experiments show, however, that apart from this retardation of the reduction of the dye the presence or absence of the iodine is immaterial.

Discussion of Results

The shade of colour produced on the mercerised material depends upon the degree of mercerisation. A range of samples of 8's lea flax line, bleached three-quarter white, was mercerised under tension with caustic soda solutions of densities rising by 10° Tw. from 20° Tw. to 70° Tw. The results of the test are shown in the following table—

Specific gravity of Caustic Soda Tw.°		Colour change
Nil	...	Bright blue, no change.
20°	...	Only very slightly redder.
30°	...	Definitely redder.
40° and 50°	...	Full purple and definitely the reddest of the series.
60° and 70°	...	Rather bluer than 40° and 50°.

An attempt is made in the accompanying plate to illustrate the different colours obtained in the above series of experiments. The shades will, of course, vary with the depth of shade of the staining by Methylene Blue, and also will not be quite the same with different materials. A yarn, for instance, may appear brighter in colour than a cloth. The relative results will, however, be the same.

While differences in the colours of the different mercerised samples shown in the table could not be considered as a very accurate criterion of the strength of the caustic soda employed in the mercerisation, it is quite possible, after some experience and by comparison with a range of known samples, to gain some information on this point.

This test has been employed on a number of different linen cloths, some of which had been mercerised under industrial conditions. Other cloths were mercerised under known conditions in the laboratory. Practically no difference has been found in the behaviour of cloth mercerised under tension with that mercerised without employing tension when mercerisation was carried out fully in each case. The test may be slightly affected by the presence of finish on the cloth, especially when mercerisation has not been carried out very fully. A very lightly mercerised material may not show any colour change at all under the standard conditions of the test if it contains considerable quantities of finishing materials. The finish apparently retards the reaction to some extent. It is advisable, in doubtful cases, to destarch the material, but the removal of the finish need not be so complete as is required by the iodine test, and in most cases is quite unnecessary. If very large quantities of starch are present, however, difficulty may be experienced on account of the reduction of the Methylene Blue. In practically any case, boiling for 10 minutes with 3% sodium carbonate solution will remove the starch to a sufficient extent.

Application of the Test to Various Materials

Tendering by boiling for one hour in sulphuric acid of concentration of 1·6 grams per litre does not invalidate the test. Pieces of linen cloth, mercerised and unmercerised, which were tendered in this way, gave the reaction exactly as the original untendered material. Mercerised and

unmercerised linen cloth which was completely rotted by soaking in deci-normal sulphuric acid and heating for one hour in an oven at 98° C., showed the colour difference almost as well as the untendered samples. A linen damask was mercerised in the brown state and, together with a similar piece of unmercerised material, was taken through the ordinary bleaching process. The test was not affected by this procedure, the reaction of the mercerised cloth being exactly the same as with similar cloth mercerised subsequent to bleaching. A small piece of the damask which had been bleached after mercerisation was tendered by prolonged treatment with chemic* of density 1° Tw., followed by the usual washing and souring treatments. Under test the cloth was shown to be free from acid and active chlorine. The sample failed to give any reaction for mercerisation by the method described. This was the only treatment either before or after mercerisation which has so far been found to invalidate the test.

With lightly mercerised fabrics in which some threads are "floated" over several others (*e.g.* for the production of a pattern), the ground-weave being of a different, closer structure, unmistakable evidence of mercerisation may be given only by the floats.

This peculiarity of materials containing floated threads has been seen also when using Huebner's iodine test for mercerisation. When the soda solution has been allowed to act to its greatest possible extent there is, of course, no difficulty in applying the reaction, because, under these conditions, the ground as well as the floats shows the purple colour due to mercerisation.

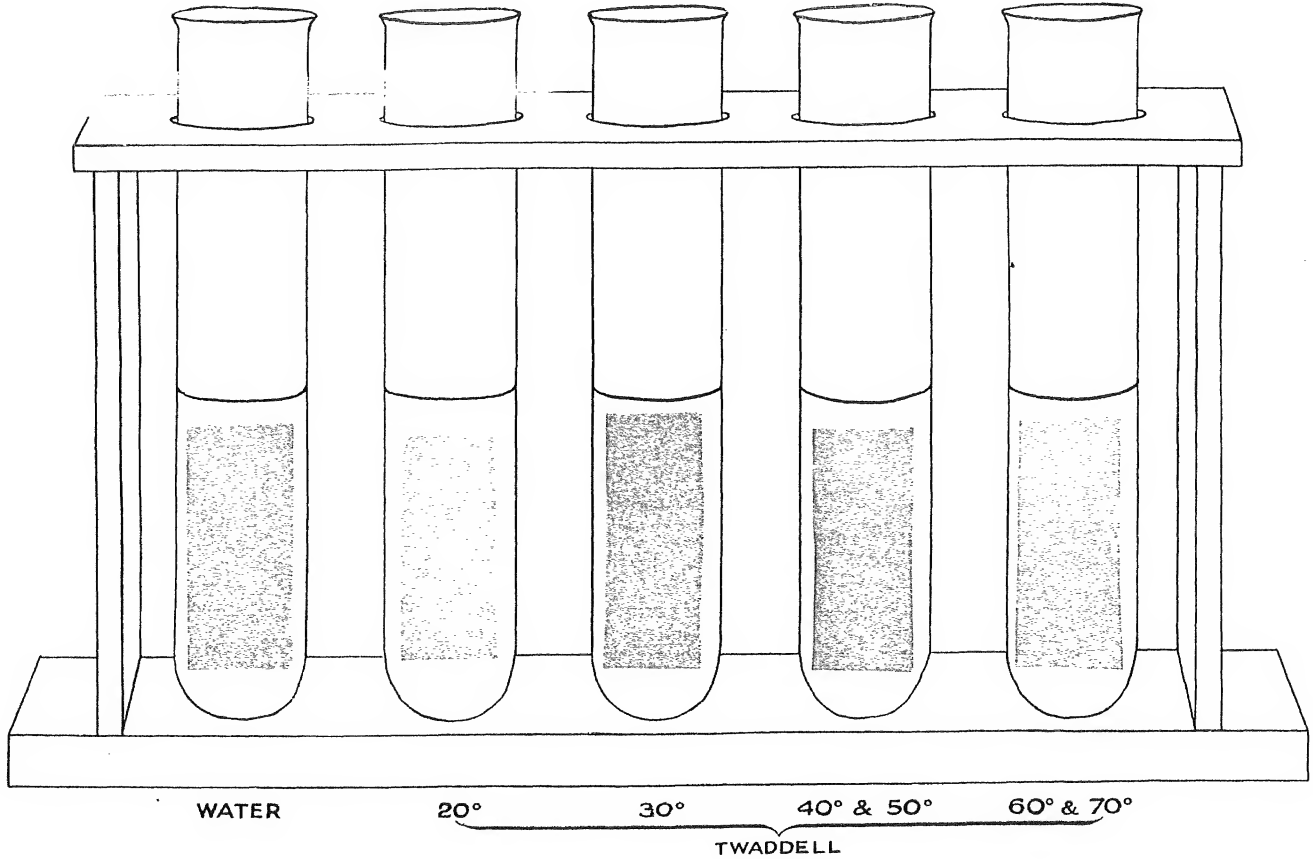
The mercerisation of flax twines, both boiled and fully bleached, has been investigated by this method and the test was found to be quite reliable in distinguishing the mercerised from the unmercerised twine.

A number of dyed linen cloths, mercerised and unmercerised, were tested; the dyes employed including both the vat and the direct type. All the mercerised samples gave a good positive reaction. In the case of the direct dyes the colour was first stripped with hydrosulphite or titanous chloride. Where the colour of the material was of a light shade it was sometimes found that the test could be conducted successfully without stripping the dye. To ascertain whether the stripping reagents had any effect on the test, undyed mercerised and undyed unmercerised cloth was boiled for five minutes with a 10% solution of hydrosulphite and a 2% solution of titanous chloride. In neither case did this treatment affect the test.

Reference to Huebner's paper† will show that the iodine test gives a satisfactory reaction for mercerisation when the material is treated with strong mineral acids, assuming the chocolate colour with a zinc chloride-iodine solution characteristic of mercerised material under this test. During the present investigation samples of flax line yarn were treated under tension with (i.) concentrated nitric acid for 20 seconds, (ii.) concentrated sulphuric acid for 30 seconds, (iii.) concentrated hydrochloric acid for 1 minute. Ramie yarns treated for three minutes with nitric acid of 82° Tw. under tension and when loose were also tested. A calcium thiocyanate solution is sometimes employed to obtain an effect similar to mercerisation. Flax line yarn was therefore prepared for testing by treating it for three minutes with a solution of this salt of sp. gr. 1·4 (boiling point of solution 135° C.) at a

*The term chemic is generally used to denote the calcium hypochlorite (bleaching powder) solution employed in the ordinary bleaching process.

† *Ibid.*



WATER

60° & 70°
TWADDELL

temperature of 90° C., after which it was washed, soured, washed, and dried. The following table shows the results obtained in this series of experiments.

	Mercerisation Agent	Colour change
Flax	1—Nitric acid (83° Tw.)	... A slight change towards purple, very similar to that obtained with yarn mercerised with caustic soda of density 30° Tw.
	2—Sulphuric acid ... (169° Tw.)	... Colour change same as with nitric acid (1).
	3—Hydrochloric acid (33° Tw.)	... Colour change not quite so marked as with 1 and 2. May be compared with yarn mercerised with caustic soda of density 20° Tw.
	4—Calcium thiocyanate (80° Tw.)	... Result very similar to that obtained with nitric acid (1). Colour is slightly redder.
Ramie	5—Nitric acid (82° Tw.) Mercerised loose	... Slight colour change. Very similar to the result on flax shown above (1).
	6—Nitric acid (82° Tw.) Mercerised under tension	... Same as previous experiment (5).

Flax yarns which had been mercerised under tension with caustic soda solutions of density 50° Tw. and 60° Tw. were remercerised by treating under tension with concentrated nitric acid 83° Tw. for three minutes, washed, and dried. The colour change produced was the same as that obtained with the yarn which had been treated with caustic soda alone. It will be seen that the iodine test and the present reaction give, in conjunction, a method of distinguishing material which has been mercerised with acid from that which has been mercerised with caustic soda. If the iodine test gives a positive reaction while the Methylene Blue-carbonate method gives a negative or very slight positive result, one may be fairly certain that the material has been treated with a solution of a substance other than caustic soda.

Cotton cloths mercerised and unmercerised behave, under this test, in the same way as linen cloths. When testing cottons it was found that the 3% solution of carbonate produced a slight change towards violet in the unmercerised material. A similar slight change is produced on unmercerised linens by a 7% solution of carbonate or a $N/50$ solution of sodium hydroxide. The carbonate solution for cottons should not be stronger than 1%, which acts on cottons much in the same way as does a 3% solution on linens.

Further experiments have been made employing mercerised and unmercerised flax, ramie and hemp yarns, bleached and unbleached. The mercerisation was carried out by treating the yarns under tension with caustic soda of density 40° Tw. for three minutes. A 3% carbonate solution was used as the reagent throughout the series of tests. The results obtained are shown in the following table—

Yarn	Colour change
Bleached flax mercerised ...	... Full red purple.
,, unmercerised	... Unchanged.
Bleached ramie mercerised	... Red purple.
,, unmercerised	... A slight change towards violet is produced.
Unbleached ramie mercerised	... Red purple.
,, unmercerised	... A slight change as with the bleached yarn.
Bleached hemp mercerised	... Red purple.
,, unmercerised	... A rather greater change than with the corresponding ramie yarn.
Green hemp mercerised ...	... Purple colour fairly good, but it is masked a great deal by the colour of the yarn.
,, unmercerised ...	... Same as with bleached yarn. The colour of the yarn is again a difficulty.

It will be seen from this table that the 3% carbonate solution is not satisfactory for testing ramie or hemp. Quite a considerable colour change occurs with unmercerised bleached hemp. The difference between mercerised and unmercerised ramie and hemp materials is readily seen, however, if a 1% carbonate solution is used. The reaction might therefore be employed as a qualitative test for hemp in flax materials. Thus, if a change occurs in a reputed flax material, which is known to be unmercerised, when employing a 3% carbonate solution, it may be suspected that it contains a certain admixture of hemp fibre. There are, however, other more trustworthy tests for hemp. This difference in the behaviour of flax and hemp may be of considerable importance when employing the test. A reputed pure flax unmercerised material after preparing with the Methylene Blue solution and tested with a 3% carbonate solution may react as though slightly mercerised when the colour change is really due to adulteration of the flax with hemp fibre. A test for hemp* should be made if there is any doubt as to the purity of the flax material.

The possibility of using alkalis other than sodium carbonate has been investigated. Sodium hydroxide in concentration of $N/50$ is fairly satisfactory but produces a slight change towards violet with the unmercerised material. Sodium hydroxide solutions weaker than $N/50$ will produce the purple colour characteristic of mercerised material but have the disadvantage that they require to be heated a considerable time, and the Methylene Blue colour may be entirely stripped before the reaction takes place. $N/25$ sodium hydroxide produces quite a strong purple on unmercerised material on warming very slightly and will also change the colour a little in the cold. $N/10$ sodium hydroxide changes the colour of both the mercerised and unmercerised material to purple very rapidly in the cold.

Potassium and lithium hydroxides react similarly to sodium hydroxide of the same normality. Potassium carbonate gives results exactly similar to those obtained with sodium carbonate. Ammonium hydroxide and ammonium carbonate give no appreciable colour change even in high concentration. Saturated lime water gives the reaction quite well, but also attacks the unmercerised material to a slight extent, rather more than does $N/50$ sodium hydroxide.

None of these alkalis has any advantage over sodium carbonate. The hydroxides all change the blue colour of the unmercerised material towards violet to a slight extent. This is of little importance if one is merely comparing two samples, but is a great disadvantage when testing an unknown material. The value of the carbonate, either sodium or potassium, of the correct strength for the material under investigation, is that it leaves the colour of the unmercerised sample unchanged, so that if a blank experiment is carried out side by side with the sample to be tested by boiling a piece of the tinted material with distilled water, absolute certainty can be attained.

Methylene Blue was the dye mainly employed in these experiments. A similar result was obtained with Methylene Violet. The Methylene Blue was the pure hydrochloride, free from zinc. The commercial zinc chloride compound with Methylene Blue may, however, also be used if reasonably pure. A number of other basic dyes were examined but no corresponding result was obtained.

*C. R. Nodder, J. Text. Inst., 1922, **13**, 161; Linen Research Inst. Memoir No. 7 gives a rapid and convenient test for hemp and flax, depending on the twisting behaviour of these fibres on drying, flax twisting clockwise and hemp anti-clockwise when the free end cf the fibre is directed towards the observer.

SUMMARY

A new test for mercerisation is described. A small sample of the material is stained with Methylene Blue and heated with a dilute solution of sodium carbonate under standard conditions. Under this treatment the mercerised material turns reddish-purple, the unmercerised remaining blue. It is possible by comparison with a range of known samples to estimate the approximate concentration of the caustic soda employed in the mercerisation.

Materials mercerised with strong mineral acids behave differently under this test from those mercerised with caustic soda, a result which in conjunction with the positive reaction obtained with the iodine test makes it possible to distinguish these materials.

21—RANCIDITY AND OXIDATION OF FATTY OILS IN REGARD TO WOOL LUBRICATION*

By W. Rhys-Davies

INTRODUCTION

The subject of wool lubrication covers an extensive field throughout the textile industries and has not received detailed theoretical study. It is of the greatest importance, not only in itself, but in the subsequent operations of cloth finishing. Spinning oils vary from the high-priced olive oils for the fine worsted yarns to the so-called "black and brown oils" obtained from recovery plants. For the purposes of this dissertation it is my object to concentrate and deal with the problems connected with one branch of the wool textile industry, namely, the worsted trade, and to put forward observations extending over many years.

The requirements of a spinning oil are primarily those of a lubricant—oiliness—low viscosity to prevent choking of the card clothing and combs, non-corrosive properties (low acidity), high flash point, and absence of any staining effects. The textile value of oils, as far as the worsted industry is concerned, is largely regarded from the standpoint of the amount of free fatty acids, expressed as "oleic acid." It is just as essential to remove the oils from the finished cloth, preparatory to dyeing, as it is to utilise them in the earlier stages of carding, combing, and spinning. These requirements were considered in the trade to have been met by the use of commercial grades of olive oils, because, in their original state, they are clean in working, non-staining, fairly neutral, and easily emulsified with soda and soap in the scouring process. Olive oil is classified as a non-drying oil, and as a wool lubricant was considered to be immune to changes when in contact with wool fibre in the form of tops and yarns. It will be shown how much change takes place in vegetable oils during contact with fibres.

Whilst it is essential for the paint and varnish industry to use oils whose drying properties are paramount, the textile industry, on the other hand, generally requires those oils as lubricants which do not dry and produce hardened films on the fibre, since such films cause great difficulty in the subsequent operations of scouring, dyeing, and finishing. The whole problem concerning these changes is one of practical importance, and a solution of commercial value is very desirable since expensive oils, such as olive, should not degenerate in textile practice, but retain the properties of original oiliness and viscosity for a period of several months.

PHYSICAL AND CHEMICAL CHARACTERISTICS

The general characteristics of the oil extracted from wool tops and worsted yarns are—

(1) A darkening of the oil.

(2) Distinct differences in odour and taste (rancid).

* This paper was read by Mr. George F. Pickering at a meeting of the Yorkshire Section of the Institute on 15th April. The discussion thereon follows on pages T230—T232

(3) The oil is much more viscous.

(4) Increase of refractometer figures.

(5) An ever diminishing iodine value.

(6) Increase in the "titre" of the insoluble fatty acids.

(7) Notable rise in specific gravity.

(8) The oxidised oil acids become chromogenetic and stain wool, either as sliver or yarn, a brownish-yellow colour, not removable in scouring by any known chemical agent.

(9) The oxidised portion of the mixed fatty acids has a characteristic insolubility in petroleum ether but ready solubility in strong alcohol, hence they can be determined quantitatively.

(10) There is notable increase in mean molecular weight.

CHANGES AND MODIFICATIONS ON FIBRES

It is found that all vegetable oils, including the so-called non-drying group, become considerably changed after prolonged contact with textile materials, as the amount of oil used is relatively small and the surface, to which the oil is exposed, enormously great. For example, a fine botany wool top, oiled with 3% of olive oil, gradually assumes a different character. The oil becomes more acid and, with increasing hydrolysis and consequent production of free fatty acids, rancidity develops with concurrent oxidation of the free fatty acids and normal glyceride oil. The oxidised oil acids so formed are dark brown, varnish-like, and sticky to the touch. It is well to remember that some forms of oxidised acids are stickier than others, and that some may become quite firm, which properties may be due to differing degrees of oxidation or to the respective amounts of the two unsaturated liquid acids which have become oxidised. Before this can be definitely proved, much more work is required to be carried out.

Acidity as Free Oleic Acid

The commercial brands of olive oils used in the worsted industry, for the most part, do not contain more than 5% of free fatty acids. From observation by the writer, the amount of free acidity originally present in the oil does not appear to influence the objectionable changes which proceed on oiled tops and yarns. Within a few months the oil becomes so rancid and thickened as to give acidity figures of 15% and more. It is not to be inferred, however, that the high acidity figures produced are a measure of the amount of "rancidity," since rancidity has no numerical value. Most probably rancidity may be regarded as a state or condition of the oil which develops concurrently with oxidation. From long experience in the wool textile industry, it is realised that acidity is always accompanied by degradation of the original oil into oxidised products to the extent of approximately 5% to 18% of the weight of oil extracted from the wool top, but these products may also occur to a greater extent than the acidity formed would indicate, showing oxidation of the neutral glycerides present to have occurred.

But even these percentages are often exceeded, depending upon the quality of the oil, that is, the nature and composition of the mixed fatty acids, since olive oil is composed of the glycerides of the solid acid, palmitic acid, and the two liquid acids, oleic and linolic acids.

Products of Oxidation

Oxidised oil acids appear to be the final products of oxidation consequent upon the production of rancid mixed fatty acids containing ethylenic linkages, and their formation is common both to vegetable and animal oils under the same conditions. Further, it has always been recognised in the trade that oiled tops and yarns eventually become "tacky" to the touch and, at a later stage, even sticky. Since this always occurs after the use of adulterated oils, the erroneous explanation has been that the olive oils used must have been adulterated or admixed with inferior oils of the semi-drying or drying classes. Moreover, olive oils are regarded as inert by the larger section of the trade, and therefore immune to changes due to air oxidation when used for wool lubrication.

TECHNICAL DEFECTS CAUSED BY THE OXIDATION OF WOOL OILS

In the worsted industry there has been, and still continues to be, great financial loss, especially in dyed goods, caused by the presence of oxidised oil on the fibres. These defects are often only revealed in dyed pieces when an abnormal degree of variation of shade is observed. The special faults in question are most noticeable on piece-dyed worsteds in various weaves. The fabrics often show streaks and bars, which sometimes run with the warp and sometimes with the weft, and if yarns have been used after long storage for both warp and weft, very irregular uneven dyeing takes place. There are many instances where the presence of oxidised oil has been observed when the pieces have been perched in the grey, prior to dyeing and finishing. Extraction by means of petroleum ether showed in these areas oily matters of greater viscosity than normal oil; on analysis, oxidised oil acids were found to be present in much greater amount than in the oil extracted from the non-stained portion of the cloth.

Oxidation of Olive Oils

Richardson and Jaffé (*J. Soc. Chem. Ind.*, 1905, **24**, 534) find that some olive oils thicken and become gummy by oxidation much more readily than others, and are therefore less suitable for oiling wool. This property has no necessary relation to the "free fatty acid" content, the source of the oils being of far greater importance. Their method of testing the oxidisability of an oil is to place 10 grams of the sample in a tin tray measuring $4 \times 6{\cdot}5 \times 0{\cdot}5$ inches, and placed in a special oven, and to pass over the oil a current of air heated at 100° C. for six hours, or at 204° C. for four hours. They then determine the time of efflux at 100° C. of 5 cc. (before and after heating) of oil by means of a jacketted 5 cc. pipette. They give the following figures—

Table I.

Description of oil	Free Oleic Acid	Percentage increase of Viscosity after heating: 6 hours at 100°	4 hours at 204°
Gallipoli	21·30%	10·5%*	—
Seville	3·82%	32·6%*	—
Gallipoli	4·23%	—	73%*
Seville	4·23%	—	644%*
Levant	12·69%	—	315%*

*This increase in viscosity is, of course, due to the oxidation which has taken place.

Hyland and Lloyd (*J. Soc. Chem. Ind.*, 1911) state that owing to the production of partially hydrogenated oils having chemical and physical

values similar to those of olive oil, such are being placed on the market as substitutes for olive oils for use in the worsted trade. They go on to state that these substitutes have an iodine value almost equal to that of genuine olive oil, but, unlike olive, gradually become "tacky" when exposed in thin films to moist air, as, for instance, on oiled tops. . . . Accepting these findings to be true in regard to "substitute oils," not necessarily hydrogenated products, they have overlooked the fact that genuine olive oils are subject to the same fault which is common to all fatty oils—vegetable and animal—possessing unsaturated fatty acids. It is only a matter of degree.

EXPERIMENTAL

Before dealing with the analysis and examination of the oils extracted from wool tops and yarns, it would be well to give typical results of analyses of commercial oils used as wool lubricants to be followed by analytical data obtained on some oils after removal by petroleum ether from "tops."

Table II.

Referring to the analyses of typical olive oils, the data shown in Table II. adequately conform to the requirements for genuine commercial oils. The iodine absorption values are quite normal and adulteration with other possible oils was found not to have been done. The practical utility, however, of these oils is different.

Some oils will degenerate and oxidise more rapidly than others on the wool fibre, although their iodine numbers are very similar and their free acidity figures not far removed.

Again, one oil having an initial acidity of 2·82% and no apparent traces of oxidised products, will after contact with clean scoured wool (3% of oil on the weight of wool) give figures as follows—

	1st Month	2nd Month	3rd Month
Acidity as free oleic acid	5·70	10·97	12·11%

Comparing the analyses of the "top oils" in Table III. with those of olive oils in Table II., it is shown that characteristic changes have taken place. All four extracted oils were found to be rancid, using the Kreiss test. There appears to be no doubt that polymerisation of the normal oil takes place whilst atmospheric oxidation proceeds.

Amongst the decomposition products found are aldehydes, lactones, hydroxy-acids, peroxides, and volatile acids, which are identified by the ordinary methods of analysis. During the examination of oils extracted from textile materials for nature and quality, the decomposition products mentioned, other than the oxidised oil acids, are lost in the processes of cleaning up, and preparation for, the quantitative separation of the oxidised oil acids. In the matter of peroxide formation, it is desirable to mention here that "peroxides" are found in commercial olive oils where high acidity oils have been lowered by treatment with alkali to meet the requirements of the trade for free fatty acid content of under 5%. The influence of these peroxides on the rate of oxidation of an oil will be mentioned in the discussion on the Mackey Cloth Oil Tester.

The results of analysis of the oil as extracted from oiled wool material require interpretation. The outstanding characteristics are the high unsaponifiable oil figures, increased free fatty acids, and reduction in amount of the insoluble fatty acids, together with lowered iodine values and increased mean molecular weights.

i.—The unsaponifiable portion is always a variable and depends upon how thoroughly the wool has been scoured, for in no instance is all the grease removed in scouring, as it is necessary to retain softness in handle. Therefore these figures represent the sum of the unsaponifiable part of the olive oil (0·6% to 1·8% approx.) and the unsaponifiable matters of wool grease (35% to 40%). Often mineral oil is found, especially where such oil enters into the composition of a carding oil.

ii.—Although wool is originally lubricated with olive oils of low acidity, it is suggestive that natural hydrolysis proceeds in the same manner as with oil stored in tanks. (*See* Lewkowitsch, "Oils, Fats, and Waxes," Vol. I., on "Hydrolysis.")

iii.—The total mixed acids in the analyses correspond to the figures representing the original insoluble fatty acids, but they are not constitutionally the same. Those calculated on an oil free from unsaponifiable matter are normal in amount where oxidation is not far advanced, but where oxidation has proceeded further the total acids decrease. There is no

definite information obtained as yet, but repeated examinations show that they contain "hydroxy-acids" which yield to acetylation.

iv.—The mean molecular weight is always found to be higher than that of the fatty acids from normal oils, and apparently increases in proportion to the amount of hydroxy-acids formed and also to the presence of wool grease fatty acids, which have a mean molecular weight approximating to 340.

More investigation is necessary before any definite and reliable information can be obtained which will give satisfactory explanation of the changes experienced by fatty oils.

Separation of the "Oxidised Oil Acids"

A known weight of the filtered, clean, extracted oil is taken, titrated in neutral alcohol for acidity, then saponified with alcoholic potash in the usual manner. The unsaponifiable oil is removed by repeated extraction in separators with petroleum ether. The lower alcoholic solution, together with the washings of the petrol layers, is transferred to a beaker and evaporated until non-alcoholic. The contents of the beaker are dissolved in hot distilled water, transferred to a separator, decomposed with mineral acid, cooled, and the whole shaken with petroleum ether.

The separator and its contents are allowed to stand until the petrol layer has completely separated and the acid layer has become clear, when the lower acid layer is run into another separator and the shaking with petroleum ether repeated. The oxidised oil acids can be caused to adhere to the sides of the separators in the petrol layers. The acid liquor is run away and the petrol extracts washed with warm distilled water until free from mineral acid. The petrol solution is passed through a dry filter paper and the oxidised oil acids thoroughly washed with petroleum ether to remove any adhering petrol-soluble fatty acids. The oxidised oil acids are very soluble in warm alcohol and are readily removed from the sides of the separators and from the filter paper. The alcohol solution containing the oxidised oil acids is transferred to a weighed CO_2 flask, the alcohol evaporated off, and the flask and its contents dried in the water-oven and finally weighed. For obvious reasons, it is preferable to saponify again the weighed-off oxidised oil acids and repeat the separations in order to finally obtain a product giving constant values for "neutralisation number" and "mean molecular weight."

SEPARATION AND DETERMINATION OF THE SOLID AND LIQUID ACIDS (Gusserov-Varrentrapp Method)

This method, known as the lead-salt-ether process of separating the solid from the liquid fatty acids, can be considered at best as only approximately quantitative. No doubt the best results are obtained when the extractions with ether are carried out at very low temperatures, as in an ice chest, and the liquid oil acids dried in a water-oven through which passes a continuous current of dry carbon dioxide gas.

Analysis of the Liquid Acids

Lithium Method after Dr. C. W. Moore—After determining the iodine value of the mixed liquid acids they are dissolved in absolute alcohol, using 20 cc. per 5 grams of the mixed fatty acids taken. To the solution are added 20 to 25 cc. of a saturated solution of lithium hydroxide.* It is better to

*In Alcohol—*Author*

regulate the amount of lithium hydroxide so as to just neutralise the fatty acids to phenolphthalein indicator. When left, preferably overnight, a crystalline precipitate of lithium oleate is obtained which is collected on a filter and washed with 70% alcohol. The oleate formed is then decomposed with hydrochloric acid, the liberated oleic acid taken up with methylated ether, the ether solution transferred to a weighed, wide-mouthed, stoppered CO_2 flask, and the ether distilled off in a current of dry carbon dioxide, and the residue quickly dried and weighed. By this method an oleic acid is obtained yielding an iodine value varying between 89 and 91, and a mean molecular weight of 280 to 283—theory requires an iodine value of 90·04 and a molecular weight of 282. The method is found to be very satisfactory for types of oil containing but two liquid acids.

The filtrate—the alcoholic lithium solution—is evaporated carefully until free from alcohol, transferred to a separator, and decomposed with hydrochloric acid, the liberated fatty acid dissolved in low boiling point petroleum ether, the petrol layer washed free from mineral acid, allowed to stand over granular calcium chloride, and finally run into a stoppered CO_2 flask. The bulk of this petroleum ether is distilled off, leaving only about 20 cc. A slight excess of bromine is added, the flask is attached to a reflux condenser, and the liquid boiled gently for some time, then allowed to cool gradually. Crystals of the tetrabromide of linolic acid separate out, the melting point of which, after recrystallisation from petroleum ether, approximates to 114° C.

This latter separation is merely qualitative as far as this work is concerned; the linolic acid was never directly determined, the amount being calculated from the observed iodine value of the mixed liquid acids. The separations thus effected cannot be considered as absolute, but, as all the operations are carried out under conditions almost identical, the results obtained can be regarded as usefully comparative.

In the case of all olive oils, from whatever source, the liquid fatty acids have had an iodine value beyond 90. When all considerations are taken into account, namely, the lengthy and tedious separations, and, most important, the susceptibility of the unsaturated liquid acids to oxidation, it is found that the practical performance of an oil and its general suitability for oiling wool and yarns can be best determined by an apparatus which gives directly the rate of oxidation within two to five hours, according to the relative proportions of the three constituent glycerides and "free fatty acid content." Most commercial olive oils consist of the glycerides of palmitic, oleic, and linolic acids in varying quantities, and, only in isolated cases, does one meet with an olive oil containing the two solid acids, palmitic and stearic, together.

MACKEY OIL TESTER

This apparatus is a cylindrical copper water-bath of special design. Its construction is suitably described in Lewkowitsch, "Oils, Fats, and Waxes," Vol. III. The instrument was designed for the purpose of testing the lower-grade oils used by woollen manufacturers, for suitability for oiling wool, which oils have to meet certain requirements in regard to fire insurance. The tester has been found, however, to have wider application; it can be used for the practical valuation of the more expensive wool lubricants, namely, olive, arachis, and blended vegetable oils sold as olive oil substitutes, for it indicates their comparative rate of oxidation, and thus reveals the presence of more or less unsaturated fatty acids.

As far as one can judge at present, the degradation products after heating the oils on fibre through the apparatus are the same as those obtained by slow atmospheric oxidation. In any case, the resinous oxidation product is the same as that produced on oiled tops and yarns, and this is really the fraction which is of most concern to the textile industry. For this reason the behaviour of oils in the Mackey Tester has been regarded as directly comparable with that obtaining in textile practice.

Briefly stated, it is found that this apparatus, for all practical purposes, affords reliable indications in physical and chemical directions as to the behaviour of oils in practice when used as wool lubricants, and therefrom enabling judgments to be passed as to the nature of the mixed liquid fatty acids. Whilst the iodine value possesses certain merits as a source of information regarding normal glyceride oils it has to be somewhat discounted as applied to variations of normal oils which, while not sufficient in themselves to show marked differentiation in iodine number between good, medium, and unsuitable oils, are all important from practical considerations. From observations it is inferred that the determination of the iodine absorption number for the valuation of oils has been much overrated, and cannot be considered alone as affording a safe criterion of judgment. Consequently, the utility of the Mackey Tester assumes a position of high importance for trade purposes, providing, as it does, direct information replacing several chemical determinations of hitherto unappreciated value, such as the Maumené, Livache, Bromine Thermal, and modifications of the various "heat-oxidation" tests.

EXPLANATION OF TABLES IV. TO VI.

Tables IV. and V. are intended to show the remarkable variations in the rate of oxidation, which in some cases approximates to spontaneous combustion, on heating in the Mackey Tester. The figures are taken promiscuously from a daily record of olive oils tested for commercial purposes in this manner, and on examination it will be observed that in some cases an oil having comparatively low iodine value and low initial free acidity figures has increased in temperature more rapidly than an oil possessing higher iodine value and acidity. These findings appear to substantiate the general inferences and statements made throughout this work.

Table VI. sets forth experimental results involving chemical separations of the mixed fatty acids and the determination of the iodine numbers of the mixed liquid acids, with the amount of linolic acid calculated therefrom. The rate of oxidation in these cases bears a closer relation to the iodine value of the mixed liquid acids, which supports the usefulness of the Mackey Tester.

In connection with the analyses and subsequent Mackey tests of the two samples marked F118 and G1332 respectively, it was decided to saponify these oils in the usual manner, together with a sample of edible olive oil, marked F.M.R., and to obtain their respective mixed fatty acids on which to carry out standard Mackey tests.

TESTS UPON OLIVE OIL FATTY ACIDS

Reference	*F118*	*G1332*	*F.M.R.*
Temperature reached after heating for 35 minutes	91·1	87·8	88·5
Time in minutes required to reach 193° Centigrade	72	168	85

From the above it seems safe to assume that the amount of original free acidity in the normal oil plays a comparative part in the rate of oxidation only when the compositions of the olive oils are approximately identical, but where these latter compositions are different the amount of free acidity in the original oil ceases to be any criterion. A result such as this on the actual separated mixed fatty acids appears to confirm the statement of Lewkowitsch ("Oils, Fats, and Waxes," Vol. I., Chap. III.), in discussing the preparation of oleic acid, that "exclusion of atmospheric air, although desirable, is not an essential condition, for the older statements, that oleic acid absorbs oxygen from the air with avidity, are erroneous. These statements are due to the fact that the fatty acids from linseed oil or semi-drying oils were previously termed oleic acid."

Since the above, further tests have been made on similar lines with equally satisfactory results. In each case it has been found that the time taken in oxidation of the mixed fatty acids and the iodine value of the mixed liquid acids are inversely proportional.

IODINE VALUE IN RELATION TO THE MACKEY TESTER

It is perhaps advisable to state here that experiments have been carried out by adding definite amounts, up to 15%, of palmitic acid, as representing a solid acid, to normal olive oil. Mackey tests on these mixtures showed that the rate of oxidation was not materially influenced, although the iodine value diminished *pro ratio.* Although the iodine value is a measure of the unsaturation of an oil, that is, a measure of the comparative number of ethylenic linkages, it does not indicate the relative stability of such linkages; in other words, the iodine value, although indicating the final limit to which an oil can be oxidised (destructive methods excluded), *does not show the general tendency* of an oil to oxidise.

SUMMARY

All temperatures, unless otherwise stated, are expressed in Centigrade degrees.

In no case has the temperature in the Mackey Tester been allowed to exceed 200° Centigrade for obvious reasons.

1—The requirements of oils for wool lubrication have been shown.

2—The nature of and effects upon oils modified by exposure to actual operative conditions have been outlined.

3—The varying amounts of linolic acid glyceride, from negligible to dangerous percentages, in commercial olive oils, have been shown to be

a primary cause of inequalities in the rate of oxidation from a practical point of view.

4—The extended use of the Mackey Tester is shown to provide reliable, direct indications of the degree of unsaturation, and consequently of relative suitability of commercial oils.

5—Practical tests on a working scale have borne out results as shown in the tables herewith.

Discussion

Mr. W. S. Stansfield said Mr. Rhys-Davies quoted Lewkowitsch as saying that "the older statements that oleic acid absorbs oxygen from the air with avidity are erroneous." That was not his experience. He had known instances of goods containing oleic acid being moistened and then dried, and within twelve hours they had fired.

Mr. Pickering (replying on behalf of Mr. Rhys-Davies) said that many sins were attributed to oleic acid for which oleic acid was not responsible. The question was whether it was pure oleic acid. He thought it was somewhere about 1876 that it was discovered that the addition of a certain quantity of linseed oil fatty acids to the distillates enabled the oil manufacturer to carry out his processes more easily, and from that time to the present the resultant oil had been sold as oleic. Unless actual analyses were made of the oil before it was put on to the goods, it was hardly fair to attribute the results to oleic acid.

Mr. J. B. Speakman said the difference in the results obtained might be due to the fact that in the case of the actual goods there was a small quantity of oil spread over an immense surface, whereas in the laboratory there was a relatively large bulk of oil on a small surface.

Mr. Pickering said that, on the other hand, the rate of oxidation on wool was only a fraction of what it was on cotton, and in the Mackey tester cotton was used. Commercial oleic acid was by no means pure oleic acid; in fact, he himself had been unable to prepare pure oleic acid in the laboratory.

Mr. G. E. Cowlishaw said his own experience was that all the commercial oleins contained a certain amount of linolic acid.

Mr. Stansfield said he had hoped that Mr. Rhys-Davies would have illustrated the detrimental effect of the oxidation of oils on wool. In specific cases it was very difficult to prove that the trouble was due to oil.

Mr. Rhys-Davies said the paper was only the first portion of the work he had in hand. He intended dealing with that point later.

Mr. Cowlishaw asked whether any gentleman present could give any information as to the acceleration of oxidation on wool due to the presence of water.

Mr. Speakman said oxidation would not take place unless some water were present.

Mr. Pickering said he had seen some flannel goods stored in a defective warehouse, and at the points where water had come through there was a small circular stain at the top, gradually increasing in size with each layer, until at the bottom the stains were 18 inches in diameter. The goods were in the grease, waiting to go to the finishing. He had not been able to obtain

evidence from the Mackey tester with regard to the effect of water, but in that respect the behaviour of cotton was different from the behaviour of wool; and it was a point well worth examination.

Mr. W. M. Mackey said that so far as the Mackey tester was concerned, one had to be careful not to let steam get into the apparatus. If water got in, undoubtedly it had a quickening effect.

Dr. L. L. Lloyd said that with regard to Mr. Stansfield's point, oleins were often adulterated with cottonseed oil to bring up the saponification figure, and the cottonseed oil was very detrimental to the manufacturer and the dyer. If pieces were scoured with cottonseed oil soap, the soap could not be entirely removed, and the most deleterious effect was noticed if the pieces were afterwards dyed with Coomassie Navy Blue, the dyeing properties of which were very easily modified, giving stain effects and uneven dyeing through the presence of easily oxidisable oil. He did not quite agree with the tests which Mr. Rhys-Davies had made on wool. Petroleum ether ought not to be used for separating the fatty acids.

Mr. Pickering said ether had been used, not petroleum ether.

Dr. Lloyd said he was under the impression that the paper said petroleum ether.

Mr. Cowlishaw said petroleum ether was useful for finding the worst offenders, because it would not touch oxidised fatty acids.

Dr. Lloyd said that as far as the analysis of oil was concerned, reference was made to a paper by Hyland and himself, and in that paper it was stated that the iodine value was of no use, but one must deal with the analysis of the liquid fatty acids, because it was only the liquid fatty acids that could be considered as the means of bringing about ready oxidation. With regard to analysis, it was not necessary to analyse the whole of the oleic acid. It was sufficient to use the bromine precipitation method, and determine the octa and tetra bromines. That reduced the amount of work. His own opinion was that rancidity had nothing to do with oxidation. If butter were kept in a jar fully loaded with pure salt, it would not go rancid for a very long period. On the other hand, if commercial salt containing calcium and magnesium were used, the amount required was at least double that of pure salt. It was known that pure salts prevented bacterial action, and he was pretty certain that rancidity was bacterial decomposition—not an enzyme decomposition, but a bacterial decomposition, because it would take place only in the presence of oxygen.

Mr. Pickering said rancidity would occur if the butter were sealed in a tin.

Dr. Lloyd said it would take place only in the presence of bacteria. If it were sterilised by heating it would remain unchanged.

Mr. Pickering asked what solvent Dr. Lloyd preferred.

Dr. Lloyd said he preferred tri-chlor-ethane.

Mr. Pickering said he had used acetone because it could be used cold and possessed a much lower boiling point.

Dr. Lloyd said if one kept below 80° no harm would be done.

Mr. Stansfield said he quite agreed with what Dr. Lloyd had said about mixing cottonseed oil with oleins. Cottonseed oil and cottonseed soaps were the most harmful commodities that had ever been introduced into the

textile trades. Some fifteen or twenty years ago, when Bradford was doing a very big trade with the United States in mohair brilliantines and lustres in cream, large quantities of goods were shipped in tin-lined cases, and on arrival the cotton had completely carbonised and fell away in the form of dust. The goods had been stoved, and the defect—which cost Bradford thousands of pounds—was due to the presence of a slight quantity (about 0·3%) of fatty acid from cottonseed oil soap.

A vote of thanks was accorded Mr. Rhys-Davies for his paper and Mr. Pickering for reading the paper, on the motion of Mr. Stansfield, seconded by Mr. A. Mitchell Bell.

22—THE CHEMICAL ANALYSIS OF COTTON
xiii.—SCOURING LOSSES

By Robert George Fargher, D.Sc. and Lucy Higginbotham, M.Sc.

(The British Cotton Industry Research Association)

I.—INTRODUCTION AND SUMMARY

Considering the importance of the loss in weight incurred by cotton on scouring, it is surprising to find so little accurate information in the literature. Isolated measurements, for which, however, essential details are almost invariably lacking, have been quoted by Hunger,[12] who found losses in weight of 3·5 and 4% on boiling cotton for a quarter of an hour with 2·5 and 10% sodium hydroxide solutions respectively; by Dreaper,[6] who found losses of 4·4 and 6·7% on boiling cotton for one-half and one hour with 1% sodium hydroxide, and of 5·1 and 7·3% on increasing the concentration to 2·5%; by Knecht,[14] who has stated that on scouring with lime at 35 lbs excess pressure a yarn lost 2·5%, further alkali boiling followed by a chemic increasing the loss to 4%; and by Huebner,[11] who has expressed the opinion that the scouring loss of Sea Island cotton is as little as 3%.

Trotman and Pentecost,[17,18] pointed out the necessity for accurate moisture controls, and cited figures which refer, presumably (since no conditions are given), to scouring without pressure; these indicate losses of from 3·9 to 5·3% for American yarns, and 4·3 to 6·5% for Egyptian yarns, and show a fall in the scouring loss with increasing yarn counts, but as there is no indication that the same cotton was used throughout, no significance attaches to them in this respect. They concluded, further, that potassium hydroxide was more effective in equivalent concentration than sodium hydroxide, which in turn was more effective than sodium carbonate, sodium borate, or sodium silicate, the efficiency decreasing in this order, the losses in a series of comparative experiments being as follows—

Potassium hydroxide	5·0%
Sodium hydroxide	4·4%
Sodium carbonate	3·7%
Sodium borate	2·8%
Sodium silicate	2·4%

The loss in weight on technical bleaching has been placed at 5% by de Puyster,[16] at 7·3% by Jecusco[13] (6·4% being lost by an alkali boil at 15 lbs excess pressure), and at 6·5% by Higgins.[10]

In previous communications,[1,2,3,5,7,8] the chemical properties of yarns and fabrics scoured technically under various conditions have been described.

It remained therefore to correlate these changes with the losses in weight incurred, which could be determined with accuracy only in the laboratory. The applicability of the results to industrial conditions could then be gauged by a comparison of the properties of the products with those of materials scoured technically. Such experiments have now been made in a small experimental kier designed by Messrs. Mather & Platt, Ltd. Using typical American (36s Texan), Egyptian (2/50s Sakel), and Indian (20s Broach) yarns, the caustic boil has been studied in considerable detail, whilst comparative experiments have been made with the two other alkalis commonly employed—lime and sodium carbonate. Further, the behaviours of a number of typical cottons have been compared under standard conditions. In all cases the scouring loss, and the chemical properties of the scoured samples (residual wax, absorption of Methylene Blue, and copper number) have been determined, and their appearances compared.

The results may be summarised briefly as follows—

(1) Under conditions which reproduce the effects of normal technical pressure boiling with sodium hydroxide, different varieties of cotton lose from 6 to 9% in weight, American cottons generally showing the lowest losses and native Indian the highest, Egyptian cottons coming intermediately. There is therefore removed from cotton during normal pressure boiling from 3 to 4% of material which is unaccounted for by wax, nitrogenous constituents, mineral matter, or substances other than these which are removed by cold water or cold dilute mineral acids. A markedly higher value than 9% has been noted only in one instance—that of Pima cotton, which loses 11·5% in weight and is in this, as in many other respects, abnormal.

(2) The greater part of this material is removed on boiling without pressure, increase of temperature from 100° C. to 140° C. (that is, an excess pressure of 40 lbs) causing only fairly small changes in the scouring loss which are not necessarily greater (and indeed in the cases which have been studied in detail are actually smaller) for cottons recognised technically as difficult to scour satisfactorily than for those which require less vigorous treatment. Increase in the concentration of the alkali is almost as important a factor as increase in temperature, so far as the elimination of non-cellulose constituents is concerned.

(3) The scouring losses mentioned under (1) do not include the whole of the material in cotton which is less resistant than "normal" cellulose to the action of alkalis, and more drastic conditions of treatment cause a further increase in the scouring loss. For example, the loss is from 1 to 2% greater when 3% sodium hydroxide is used at 40 lbs excess pressure than when a 1% solution is used at 20 lbs.

(4) The loss in weight on scouring with lime is lower than that caused by sodium hydroxide in equivalent amount, treatment with lime at 20 lbs excess pressure, for example, causing a loss in weight approximately equal to that occasioned by sodium hydroxide without pressure. Contrary to previous suggestions, therefore, the effect of lime is, in this respect, much closer to that of sodium hydroxide than to that of water.

(5) The loss in weight on scouring with sodium carbonate is only slightly lower than that caused by sodium hydroxide in equivalent concentration.

The removal of wax, reducing substances, and coloured impurities is rather less effective, but the absorptions of Methylene Blue are often a little lower.

(6) The effect of water at 20 lbs excess pressure, as measured by the scouring loss and the chemical properties of the scoured material, is substantially that produced by sodium hydroxide at a much lower temperature—50° C.—but the colour of the water-boiled yarns is markedly darker.

(7) For treatments with sodium hydroxide, the absorption of Methylene Blue affords a qualitative measure of the scouring loss, the changes being greatest for temperatures below 100° C. At temperatures of 100° C. to 140° C., however, and for concentrations of sodium hydroxide from 0·5 to 3%, the changes in absorptive power, though relatively smaller, follow very closely those of the scouring loss. In this range, for equal changes in the scouring loss, the fall in Methylene Blue absorption is greater for cottons with high than for those with lower absorptive power. As a measure of the scouring loss and of the chemical purity of the scoured material, Methylene Blue absorption is not quite so reliable for treatments with lime or sodium carbonate as for treatment with sodium hydroxide, particularly for cottons with high absorptive power.

(8) As a measure of scouring efficiency, the copper number is only sensitive when the scour has been carried out below 100° C. At this point it has already reached an extremely low value.

(9) In the present experiments, the elimination of wax follows the scouring efficiency. In technical yarn scouring, however, the removal has been shown to be small and variable,[7] so in practice the value of the test as a measure of scouring efficiency is largely confined to cloth bleaching, where the changes are greater and more regular. In this case, measurements of Methylene Blue absorption and residual wax are complementary and mutually confirmatory.

II.—COLLECTION AND DISCUSSION OF RESULTS

Standardisation Experiments

In order to correlate the present work with industrial practice, the results obtained with the experimental kier have been compared with those found on a large scale.

Preliminary experiments showed that the results obtained with fabrics were in accord with those observed technically, save that the removal of fat and wax was less efficient. This was found to be due to variations in the preliminary treatment. Comparative tests were made therefore on material which had been singed and steeped technically, the chemical properties of the fabric being compared after (*a*) boiling for six hours at 20 lbs excess pressure with 1% sodium hydroxide in the experimental kier, and (*b*) after a normal technical alkali boil at 30 to 40 lbs excess pressure. The results are given in Table I and show only very slight variations such as might be anticipated from the rather higher pressure employed in the large-scale trials.

With yarns, the reverse effect was observed with regard to the wax, for whilst the Methylene Blue absorptions and copper numbers were in good agreement with technical practice, the removal of wax was invariably more

efficient. In the laboratory experiments, however, a preliminary wetting-out boil had been given with a 0·2% solution of soda ash, whereas it is unusual to give any preliminary treatment industrially, and when this was omitted the results agreed more closely. Typical figures are given in Table II. The preliminary treatment was included in comparative experiments, however, to ensure uniform scouring.

In general, therefore, the performance of the experimental kier appears to be in reasonable accord with large-scale practice, so that the scour at 20 lbs excess pressure, with 1% sodium hydroxide, which has been taken as a standard, may be assumed to represent the effect of an efficient technical pressure scour, so far as the removal of non-cellulose material and the concurrent alteration in the chemical properties of the cotton are concerned.

The Scouring Losses of Typical Cottons

It has been shown in the preceding section that treatment in the experimental kier for six hours at 20 lbs excess pressure with 1% sodium hydroxide yielded results comparable with efficient technical caustic boiling. In determining therefore the scouring losses of a number of typical cottons these conditions have been employed. The results (Table III) show that American cottons lose between 6 and 7% in weight, Egyptian between 7 and 8%, South American between 6 and 8%, native Indian between 8 and 9%, and the one Sea Island sample examined approximately 6%. In all cases the analyses of the products are characteristic of well-scoured cottons of the different varieties enumerated. Of two Indian-American samples included, one has a scouring loss typical of American cotton and the other a higher loss in the Indian range, but in both cases the analytical data for the scoured products are characteristic of American cottons. Pima cotton is quite abnormal, losing 11·5% in weight; even then the Methylene Blue absorption is very high for an Egyptian cotton or a cotton of Egyptian origin, the copper number, though small, is the highest recorded in the series, and the amount of wax remaining is abnormally high, as might have been anticipated from the amount initially present (1·5%). In general, however, the results indicate that the more detailed information recorded for three cottons—American (Texan), Egyptian (Sakel), and Indian (Broach)—covers the normal range of cottons used in the industry.

The Caustic Boil

In studying the effects of varying the conditions of treatment of cotton with sodium hydroxide, three typical cottons—an American (Texan) 36s yarn, an Egyptian (Sakel) 2/50s yarn, and an Indian (Broach) 20s yarn—have been employed, and the scouring losses and changes in the chemical properties of the products determined for a range of conditions likely to arise in normal industrial practice; the results are shown in Table IV.

Scouring Losses

It is at once evident that the greater part of the non-cellulose material is eliminated by open kier boiling at 100° C. Thus, considering the series of experiments in which temperature alone was varied, the American cotton lost 5·2% in weight at 100° C., as against 7·1% at 141° C. (40 lbs excess pressure), the Egyptian 6·8 as against 8·6%, and the Indian 7·7 as against

9·0%. The removal at the lower temperature is not, of course, wholly attributable to the action of the alkali, for the American cotton contained 2·4, the Egyptian 3·1, and the Indian 3·3% of material soluble in cold water, the losses on open kier boiling due to the alkali being therefore 2·8, 3·7, and 4·4% respectively. Thereafter the losses occasioned by increasing the temperature to 141° C. are respectively 1·9, 1·8, and 1·3%, so that the effect of excess pressure is most marked in the case of the American cotton with the smallest total scouring loss, and least in that of the Indian, with the greatest. Whilst, however, the loss in weight increases continuously with rise in temperature with the Egyptian and Indian cottons, it is practically constant above 116° C. with the American.

The experiments at 20 lbs excess pressure, in which the time of treatment alone was varied, indicate that the greater part of the non-cellulose material

is eliminated easily and rapidly, further changes being relatively slight. continuous, and similar in character to those observed in the experiments in which the temperature was varied. Thus, the result attained by boiling for six hours at an excess pressure of 40 lbs is reproduced at the end of 12 hours at the lower pressure, so that the effect of the higher temperature is principally to hasten the small, though significant, changes distinguishing cotton scoured under pressure from that scoured in the open kier.

The effect of increasing the concentration of alkali at a constant excess pressure of 20 lbs is apparently very similar, for the changes observed are small, progressive, and confined principally to the more facile removal of small amounts of relatively stable substances distinguished analytically by their absorptive capacity for Methylene Blue. Thus, the effect of the scour with 1% sodium hydroxide for 12 hours at 20 lbs, or six hours at 40 lbs, is attained in six hours at 20 lbs by increasing the concentration of the alkali to 3%.

Without pressure, the effect of the concentration of the alkali is more marked, and the experiments indicate that increase in the concentration of the alkali is almost as important a factor as increase of temperature so far as the elimination of non-cellulose constituents is concerned.

In the last experiment shown in each table, the temperature and concentration of alkali have been simultaneously raised to the maximum used during the experiments. The result is seen in a further increase in the scouring loss and a corresponding decrease in the absorptive capacity for Methylene Blue. The conditions are such as to depress emulsification of the wax, which is less thoroughly removed than when the concentration of alkali is lower.

The principal conclusions to be drawn from the scouring losses are therefore—(1) That the effect of increasing temperature over the range 100–140° C. is marked only by small increases in the scouring losses of the cottons; (2) that these increases are not necessarily greater, and in the present experiments are actually smaller, for cottons recognised technically as difficult to scour satisfactorily than for cottons which require less vigorous treatment; and (3) that the effect of increasing the concentration of the alkali is almost as marked as that produced by increase of temperature.

Changes in Analytical Characteristics

Copper Number—It will be shown in a later communication that one effect of treating raw cottons with cold water or cold dilute mineral acids is to eliminate the substances responsible for the greater part of the reducing power. Generally, the copper number after such treatment varies between 0·3 and 0·5. From this value it falls practically to a minimum on treatment with caustic soda at 100° C., whilst thereafter the changes are very small, so that as a measure of the effect of scouring the determination of copper number is of value only for temperatures up to 100° C.

Methylene Blue Absorption—In comparing the Methylene Blue absorptions of grey and scoured yarns, the quantity of cotton employed in the determinations must be reduced, as otherwise the end concentrations are so small when the absorption is high that serious errors result. For this purpose 0·5 gram is a suitable quantity to employ in place of the usual 2·5 grams. Using these conditions, the absorption by the grey yarns is

unaffected by the elimination of the constituents soluble in cold water, so that the changes measure solely the effect of subsequent treatment with the alkali. Figures obtained using this modification of the normal procedure are given in Table V, and show that the changes in absorptive power caused by alkali boiling are much greater below 100° C. than they are at higher temperatures, so that absorption of Methylene Blue reflects the scouring loss most sensitively within this range. Nevertheless the measurements recorded in Table IV show that over the range 100–141° C., and with concentrations of sodium hydroxide solution between 0·5 and 3%, the changes in the scouring losses of the three cottons are reflected fairly accurately by the changes in the absorption of Methylene Blue. These are relatively greater for cottons with high than for cottons with lower Methylene Blue absorptions; in other words, for equal additional losses in weight, the fall in the absorption of Methylene Blue is greater for the Indian than for the Egyptian yarn, and greater for the Egyptian than for the American. The additional material removed by the pressure boil from American cotton is therefore, in the mass, less absorbent than that removed from the Egyptian cotton, which in turn is less absorbent than that removed from the Indian.

Table V

Methylene Blue Absorptions, determined on 0·5 gram samples

Treatment	Methylene Blue absorption		
	Texas 149	Sakel 148	Broach 141

,, 100° C. (212° F.) ,, ,,	1·40	1·88	2·32
,, 20 lbs, with 1% caustic soda ...	1·10	1·43	2·00
,, 40 lbs, with 3% ,, ...	1·00	1·15	1·50

Wax—In the present experiments, the changes observed in the wax content follow roughly those of the scouring losses, save when the conditions are such as to depress emulsification, and therefore to some extent indirectly measure them. In technical yarn scouring, however, the removal of wax is generally much smaller, and is therefore of relatively little significance as an indirect measure of the scouring loss, but in piece goods bleaching, over the range of conditions normally encountered, the removal of fat and wax is generally in accord with the Methylene Blue absorption, and the measurements mutually check one another.

Colour Changes—Comparison of the shades of the different series of scoured samples shows the same progressive variations as the chemical properties and the scouring losses, increase of time of treatment, temperature, and concentration of alkali all favouring the production of a whiter product. The differences in the whites of the pressure-boiled samples after a standard bleach with an alkaline chemic liquor are, however, slight, and though the permanence of the white to steaming places the samples in the same order

as do the shades of the scoured and acid-washed samples, the maximum variation is relatively slight.

The Water Boil

Although boiling with water under pressure is practised as a means of preparing cotton for dyeing dark shades, there is little information as to the effect of the treatment. The results of earlier workers have been summarised previously[9] and since then it has been shown (*a*) that treatment with water under pressure prior to an alkali boil improves the white finally attained;[7,8] (*b*) that under pressure water removes very little fatty material from yarn or cloth; and (*c*) that the extract obtained by treating an American cotton with water at 40 lbs excess pressure contained mineral matter, a small amount of wax, a partly hydrolysed pectin, a saponin, a tannin, one or more sugars, volatile bases (principally ammonia and trimethylamine), volatile aldehydes and ketones (principally acetaldehyde and acetone), a volatile essential oil, and lower fatty acids (principally acetic and butyric or *iso*butyric acids).[5] The elimination of nitrogenous constituents was rather greater than that caused by cold water or cold dilute mineral acids, but much less complete than that caused by treatment with boiling caustic alkali. In the present experiments (Table VI) the American cotton lost 4·2% in weight, the Egyptian 4·2%, and the Indian 5·3%, the corresponding removals with cold water being 2·4, 3·1, and 3·3% respectively. The removal of reducing substances and of substances causing absorption of Methylene Blue was more complete than with cold water. As determined by analysis, the effect is comparable with that produced by 1% sodium hydroxide at 50° C. (122° F.), though the water-boiled cotton is in all three cases very definitely darker in shade.

The Lime Boil

It is usually stated—apparently on the authority of O'Neill[15]—that the effect of scouring with lime is practically identical with that of treatment with water under similar conditions, save that the fats and waxes are saponified and their removal thus facilitated in the ensuing treatment with soda ash after the lime sour. This view has presumably been reached from considerations of the small effective concentration of the lime and the relatively dark colour of yarns and cloths after the lime boil. It is not, however, confirmed by the present experiments which indicate (Table VI) that, as measured by removal of non-cellulose material and concurrent alteration in the chemical properties of the cotton, lime is a much more effective scouring agent than water, the effect of boiling with lime under pressure being, for example, comparable with that of sodium hydroxide without pressure, save in the elimination of coloured impurities, which is less effective when lime is employed. It should be noted, however, that the relationship between the Methylene Blue absorption after lime boiling and the scouring loss is not identical with that found in the case of the caustic boil. For the American and Egyptian cottons, the scouring loss is rather greater for both the open kier and pressure scours than the absorptions indicate, whilst for the Indian cotton the reverse is the case.

The Soda Ash Boil

No valid comparison appears to have been made previously of the efficacy of sodium carbonate relative to that of sodium hydroxide as a scouring agent. Technical experience indicates that the bottoming, as judged

visually, is less thorough, and the handle of the resulting material softer when the conditions of treatment are comparable, whilst Trotman and Pentecost[18] have stated that the scouring losses are appreciably smaller. In Table VI, the results obtained by treating three cottons with sodium

carbonate and sodium hydroxide solutions of equivalent concentration in the open kier, and of two equivalent concentrations at 20 lbs excess pressure, are compared. In general, the scouring losses are slightly less when soda ash is employed, the removal of wax is rather poorer, and the disappearance of copper reducing power is not quite so complete. On the other hand, the absorption of Methylene Blue is in some cases lower after the treatment with soda ash, so that, as in the case of the lime boil, the proportionality between the scouring loss and the Methylene Blue absorption does not hold so strictly as in the case of the caustic boil. In appearance, the scoured

material is invariably slightly darker in colour than in corresponding experiments with caustic soda, and the white after a standard alkaline bleach is slightly less resistant to steaming.

Approximate Composition of the Non-cellulose Material in Cotton

From the scouring loss of any cotton and a knowledge of the small amounts of mineral, waxy, and nitrogenous constituents still remaining, a *minimum* figure may be deduced for the amount of material other than "normal" cellulose initially present. Of this, the proportions of mineral matter and wax and resin are readily determined, whilst that of the nitrogenous material may be calculated roughly from the nitrogen content. Further, for a number of cottons of different origin the amount of material soluble in cold water has been determined and the proportion of mineral and nitrogenous constituents in this established, so that the amount of water-soluble material, excluding these, is easily calculated. (Incidentally, this includes the greater part of the reducing substances present in the unbleached cotton.) Such figures are deduced in Table VII from the results shown in Table VIII, both for the normal scouring loss at 20 lbs excess pressure with 1% sodium hydroxide, and for the more vigorous treatment at 40 lbs with 3% alkali. They show that the amount of material not included in the groups mentioned above is much greater than is usually supposed

Table VII

and that it accounts for from 3 to 5% of the loss in weight which occurs in normal pressure scouring, and for still more when the treatment is more drastic. The bearing of this on the scouring problem need not be emphasised further than to say that attempts to simplify the scouring process based on the more ready elimination of fatty or nitrogenous constituents leave out of account entirely an important and large group of constituents which are dealt with in normal processing.

III.—EXPERIMENTAL PROCEDURE

In the yarn scouring experiments, the yarn (2–3 lbs) in the form of a chain of hanks was packed evenly in a calico bag fitted to the interior of the experimental kier, so as to prevent contact of the yarns with metal. It was wetted out by boiling for one hour with a solution containing 0·2% of sodium carbonate at 5 lbs excess pressure, when the charge was being prepared for pressure boiling, but otherwise at the temperature of the succeeding boil, then washed and centrifuged, and the kier repacked and the main boil proceeded with. The liquor was heated externally and circulated by means of a centrifugal pump, the ratio of liquor to cotton being approximately 6 to 1. Every precaution was taken to ensure absence of air. At the conclusion of the boil, the spent liquor was replaced by more dilute alkali which was circulated for a short time and in turn replaced by water before the kier was opened. The yarn was then washed thoroughly in cold water, the hanks for loss in weight determinations and other analyses being further soured in dilute hydrochloric acid and again washed thoroughly prior to examination.

With cloth, the same procedure was adopted, save that the preliminary wetting out boil was replaced by a steep. Even packing of the kier was facilitated by the use of a cloth woven with split selvages, by which means a fabric 9 in. in width was obtained.

Determinations of Methylene Blue absorption,[3] copper number,[2] and residual wax[5] were made by the methods already described in detail. For the determination of scouring loss, two or more hanks of each cotton, of known weight and predetermined moisture content, were placed in the

middle of the chain and scoured, washed, soured, and again washed thoroughly as described above, and the dry weight at 110° C. determined. From the figures the loss in weight calculated on the dry weight (110° C.) of the grey yarn was determined.

23—A TEST FOR MERCERISED COTTON

By H. Mennell, A.I.C,

It has been noticed that mercerised cotton is more readily acted upon by sulphuric acid than is ordinary cotton, and that sulphuric acid of sp. gr. of 1·375, whilst having no action on cotton, has an appreciable action upon mercerised cotton. Further tests showed that if sulphuric acid, of the strength known to give a crêpeing effect to cotton fabrics (*i.e.* 120° Tw.), was diluted with formaldehyde (40% soln.) until the mixture had a gravity of 75° Tw., the action upon mercerised cotton was much increased, whilst little or no action was apparent with unmercerised cotton. The reagent used for the test is obtained by carefully diluting 320 c.c. sulphuric acid (120° Tw.) with 260 c.c. formaldehyde (40% soln.). This gives a mixture of approximately 75° Tw. The sample to be tested, together with a standard sample known to be mercerised, and a sample of unmercerised cotton is immersed in this reagent for two minutes at the room temperature. The samples are then well washed and neutralised with hot dilute sodium carbonate solution.

The effect of the acid mixture upon the samples is best shown by dyeing them with a substantive dye, and for the purpose of the test, the samples are dyed together in a very dilute boiling bath of Chlorazol Sky Blue GW, made alkaline with the addition of a little sodium carbonate. By comparing the depth of colour produced on the test sample with the colour of the known mercerised and unmercerised samples treated at the same time, it is possible to say with certainty if the sample is mercerised or not, and an approximation of the degree of mercerisation can be obtained.

The amount of dyestuff to be used to give the best results can easily be found from one or two trials, but the author has found that when using a dyebath of such a strength that it will dye the unmercerised cotton to a 0·1% shade (based on the weight of cotton), a well mercerised sample will have a depth of colour equivalent to a 0·8% dyeing.

The increased affinity for dyestuffs is shown with all substantive dyes, but Chlorazol Sky Blue GW has been chosen for the test, as it is much easier to distinguish differences of shades in blues than in other colours. If the sample to be tested is already dyed it may be stripped with sodium hypochlorite or hot alkaline hydrosulphite without affecting the test in any way.

The reagent can be used repeatedly if kept in a stoppered bottle. After standing for some time, polymerisation of the formaldehyde takes place and a certain amount of solid para-formaldehyde settles out. If such a mixture is well shaken before use, the test does not appear to be affected.

The advantages of this test can be easily recognised, as the depths of shade produced can be carefully studied if necessary, without the operator being compelled to decide immediately, whilst comparing samples, the colour of which is continuously changing as in the case of the Huebner test.

The author wishes to thank Messrs. Tootal Broadhurst Lee Co. Ltd. for permission to publish details of this test.

24—A RECORDING EXTENSOMETER

By THOMAS LONSDALE, M.Sc., A.Inst.P.

(British Silk Research Association)

SUMMARY

The paper describes an instrument for studying the properties of textile yarns and fibres. The instrument records photographically the load-extension diagram of the material under test; frictional errors in measurement are thus avoided, and after the application of a small correction a load-extension diagram with rectangular co-ordinates is obtained. The particular instrument described was designed and is used in the laboratory of the British Silk Research Association for studying the elastic properties of the ultimate fibres of silk: the design of the instrument enables methods to be used for manipulating the fibres which do not damage them before the fibre is extended in the instrument. These methods of manipulation are described.

INTRODUCTION

The instrument described in this paper, an improved form of that referred to in a previous paper (Denham and Lonsdale, *Trans. Faraday Soc.*, 1924, **20**, Part II.), was designed specially for the study of the elastic properties of the ultimate filaments of silk, but with obvious modifications, as by the substitution of heavier parts, could be adapted for the study of the elastic properties of more robust fibres and yarns. In its essentials the design of this instrument has proceeded on parallel lines to that described by Shorter and Hall (*J. Text. Inst.*, 1923, **14**, T493), which was designed for the study of wool fibres and of yarns. In both these instruments the fibre under test is mounted so that it is just taut, between two clamps, one vertically above the other, the upper clamp being attached to a spring. The lower clamp is then moved in some predetermined manner, thus producing elongations of the fibre, and the corresponding loads to which the fibre is subjected are measured by the deflection of the spring. Whereas, however, Shorter and Hall's instrument, designed for wool fibres, draws the record with a pen, the record is obtained photographically in the instrument now described. Owing to the relative fineness of the silk fibre and the consequent smaller loads to which it can be subjected as compared with the wool fibre, the frictional errors of a pen-recording system, unimportant in the uses to which Shorter and Hall's instrument is applied, make the employment of such a system inadvisable in studying the properties of the delicate ultimate filaments of silk.

In both instruments the arrangement is such that before the extension of the fibre is begun none of the weight of the lower clamp is sustained by the fibre; a relatively heavy clamp may therefore be used, by which the fibre may be firmly secured without undue manipulation which might tend to strain it.

DESCRIPTION OF THE INSTRUMENT

The essentials of the instrument are shown diagrammatically in Fig. 1. The upper clamp K is hung from one end of a miniature balance beam B

by means of a "fusee" chain, which is flexible, but inextensible under the tensions to which it is subjected here. A taut steel blade S is clamped firmly at each end to a heavy brass mount M, so that its long edges are horizontal, one edge being vertically above the other. The balance beam B bestrides this blade, the long axis of the beam being horizontal and at right-angles to the blade. The blade is 9 cm. long, ·7 cm. broad, and ·015 cm. thick.

A thin vertical pencil of light reflected from a small concave mirror attached to the beam B is focussed on a ¼-plate "Process" photographic plate held vertically in a plate holder attached to a carriage C which runs on rails, its wheels being fitted with ball bearings. The rails and the long edges of the spring S are parallel to the plane of this photographic plate. The lower clamp K^1 of the instrument is fixed to a mount which slides loosely upon two vertical parallel cylindrical guides. This mount is attached to the carriage C by a cord passing through guides; any movement of the carriage produced by lifting one of two weights W attached to it by cords passing over pulleys produces an equal movement of this clamp. The instrument is enclosed in a light-tight box.

MOUNTING THE FIBRES

A method described by W. L. Balls ("Development and Properties of Raw Cotton," page 89; A. & C. Black & Sons, London, 1914) is used. The ends of a fibre are attached by gum to the centres of the short sides of a thin rectangular cardboard frame, the fibre itself being just taut. The short sides of this frame are then gripped by the clamps K K^1, and the long sides of the frame cut away, thus leaving the fibre mounted in the clamps.

If the use of gum is undesirable, one end of the fibre is attached to a small piece of copper wire which is then used as a needle to thread the fibre through the clamps, which, in this method of mounting, are faced with flat plates of "red fibre" (a fibrous insulating material used in the electrical trades). These plates, if ground flat by rubbing them on plate glass with a fine abrasive, grip the fibres firmly without cutting or crushing them.

RECORDING LOAD-EXTENSION DIAGRAMS

When a fibre, mounted in the instrument, is elongated by suitable movements of the carriage C, the tensions to which the fibre is subjected produce torsions of the blade S which cause vertical movements of the spot of light. A curve is thus obtained on the photographic plate, the ordinates of which are proportional to the loads on the fibre and the abscissæ equal to the movements of the carriage and thus to the movements of the lower clamp. After the fibre has been broken a traverse of the carriage produces a reference line of zero load on the plate. Amounts equal to the displacements of the upper clamp have to be subtracted from the abscissæ to get the true elongations of the fibre. These displacements are approximately equal to the linear dimension of the corresponding load ordinates $\times \frac{1}{2}$ a/b—*a* is the perpendicular distance from the axis of the blade to the point of attachment of the fusee chain to the beam B, and *b* is the distance from the mirror to the plate. This correction is small; with a sacrifice of simplicity it could be rendered negligible by replacing the spring S by some load-recording system of small inertia, the deflections of which would be very small for the loads applied. These deflections would be highly magnified.

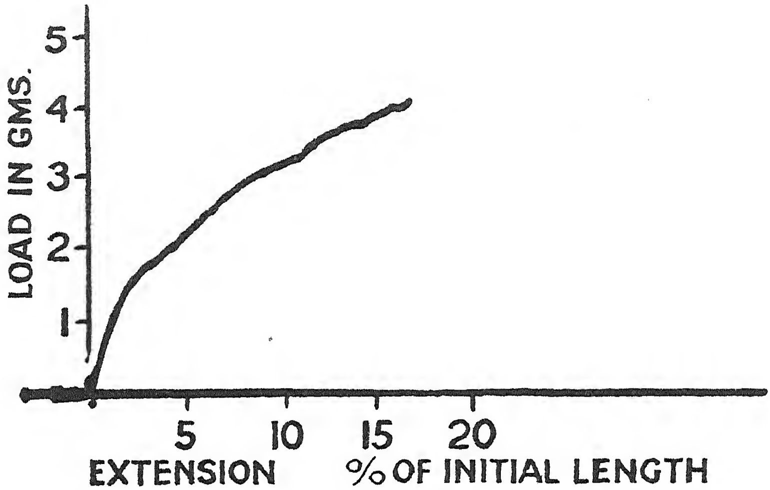

PLATE I

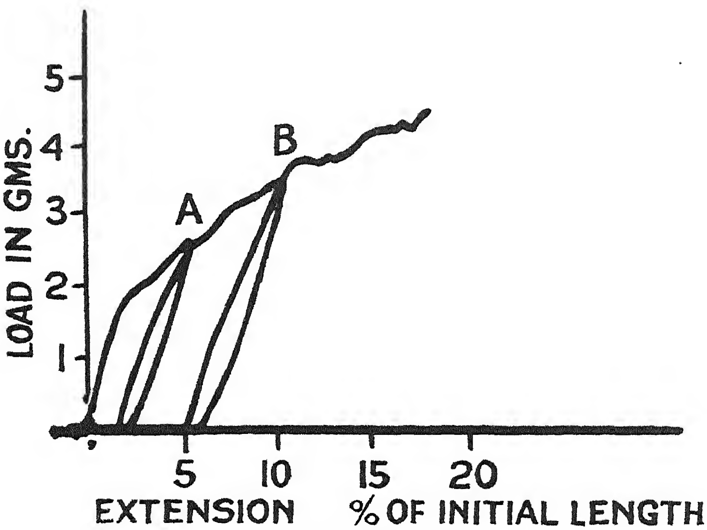

PLATE II

A circular diaphragm is perhaps the simplest of such systems. The errors due to inertia in recording systems have been dealt with by Shorter and Hall (*J. Text. Inst.*, 1923, **14**, T501).

Calibration of the Spring

The spring is calibrated by placing weights of 1 gm., 2 gm., &c., on the upper clamp and recording the corresponding deflections of the spot of light on the plate; a traverse of the carriage C is made after each weight has been put on the upper clamp. An initial traverse gives the line of zero load. A plate is thus obtained upon which are a number of parallel straight lines each corresponding to a known load. This "calibration" plate furnishes the load scale for all the curves obtained by the instrument.

An approximation to a constant rate of elongation of the fibre can be produced when required by connecting one of the weights W to a piston, which is allowed to fall in thick oil contained in a cylinder.

Plate I. shows the experimental curve given by the instrument for a single ultimate filament of mulberry silk, which has been elongated to its breaking point at a constant rate in the manner just described.

In Plate II., the carriage C was moved so that a fibre mounted in the instrument was extended to an amount corresponding to the point A on the curve; it was then moved back until the fibre was slack, and was again moved forward until the fibre was extended an amount corresponding to the point B, the carriage was then moved back until the fibre was slack, and was again moved forward until the fibre was broken. Plate II. shows the curve obtained.

The fibre shows post-elastic hysteresis; Plate II. indicates the potentialities of the instrument in studying such phenomena. The load ordinate and extension abscissa have been ruled on each photograph in order to give the curves a quantitative significance.

Testing the Instrument

If this instrument were made sufficiently massive in construction it would be suitable for the study of the properties of yarns and could therefore be tested by using it to elongate and break materials such as metallic wires, which are known to be fairly regular in their properties. The actual instrument, however, now in use in the British Silk Research Laboratory, having been constructed for the study of the properties of single filaments of silk, is, on that account, not sufficiently massive for the loads required for such metallic wires as are readily obtainable, and this actual instrument was therefore tested by means of a spring in the following manner—

Two lengths of fine steel wire, each provided with a hook soldered to its mid-point, were soldered together to form a spring A (Fig. 2). This spring was mounted in the instrument by gripping the hooks (H and H^1) with the clamps K and K^1 respectively, and a load-extension curve was obtained, using the spring A in place of a fibre. The spring A was then removed from the instrument and attached to a spiral steel spring B, as shown in Fig. 2. The system composed of the two springs A and B was then extended in a vertical direction to different lengths and the extensions of each spring were measured. The spiral spring A was removed; weights were hung on the lower end of the spring B and the corresponding extensions were measured. From these measurements and the relation obtained between the extensions of the two springs, the extensions of the spring A were obtained.

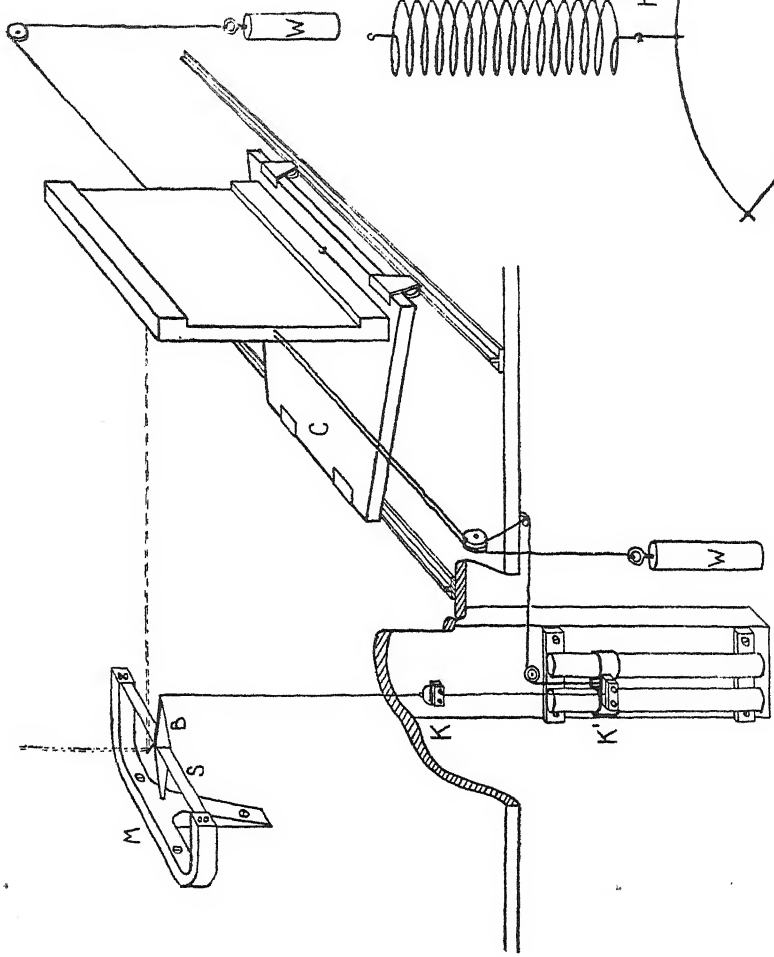

FIG. I

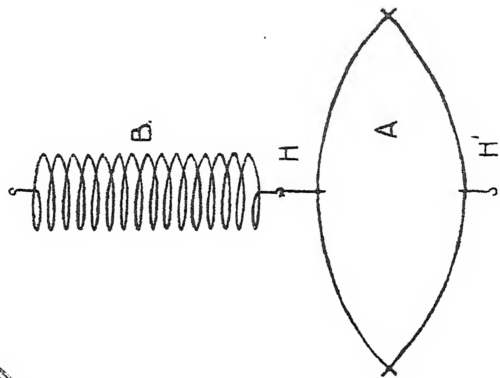

FIG. II

This procedure duplicates in the calibration, the conditions under which the spring is extended in the instrument. The following table gives the results of the test—

Test of Instrument using Spring A

Load-extension Values obtained by Instrument under Test.		Load-extension Values obtained using Auxiliary Spring B.	
1	2	3	4
Extension of Spring A	Corresponding tension	Extension of Spring A	Corresponding tension
·98	1 gm. weight	1·01	1 gm. weight
1·94	2 ,, ,,	2·00	2 ,, ,,
2·80	3 ,, ,,	2·79	3 ,, ,,
3·67	4 ,, ,,	3·61	4 ,, ,,
4·31	5 ,, ,,	4·34	5 ,, ,,
5·06	6 ,, ,,	4·97	6 ,, ,,
5·72	7 ,, ,,	5·67	7 ,, ,,

The figures in column 1 are the extensions of the spring obtained from the load-extension curve given by the instrument for the spring, which correspond to the load scale given by the calibration plate (page 4, "Calibration of the Spring"). The loads in column 4 are interpolated values obtained from the calibration of the spiral spring B and the extensions of the component springs in the systems of springs A and B. The agreement of the figures in column 1 with those in column 3 shows that the indications of the instrument can be relied on to 2%.

25—FABRIC ANALYSIS—THE CONTRACTION OF WARP AND WEFT

By Hiram Hartley
(Bradford Technical College)

INTRODUCTION

An analysis of a woven fabric is an attempt to ascertain from a pattern of a finished material the particulars requisite for its reproduction on the loom. Such analysis calls for the application of considerable skill and extensive knowledge on the part of the analyst. The influence of the processes through which the fabric has passed must be appreciated and allowed for if a reasonably accurate analysis is to be secured. Certain particulars, such as counts of warp and weft, threads and picks per inch, finished weight per yard, and the weave employed can be obtained without difficulty from the sample provided. Before, however, any of these can be converted into "loom" particulars, the contraction of the warp threads and weft picks must be ascertained. This paper describes a machine designed to measure this contraction, and the method of application of the machine.

CONTRACTION OF WARP AND WEFT

The contraction of the warp and weft threads is due to two chief causes—

(1) The bending of the threads due to their interlacing when woven.

(2) The shrinkage and movement of the fibres due to the processes of dyeing and finishing, though this is much less marked in cotton yarns than in woollen and worsted yarns.

In measuring the contraction, or actually the extension of warp and weft, the method generally employed is to stamp out a piece of the finished fabric, say 3 in. × 3 in., to pull out several threads of warp and weft, and by placing them on a flat rule to draw out the contraction with the finger and thumb, and to measure the extension as accurately as possible. The objections to this method are—

(1) That the extension of the full 3 in. can only be measured with part of the thread held by the fingers and accuracy of reading is sacrificed.

(2) That the tension applied to each thread must vary owing to the human element.

(3) That the tension applied to yarns of fairly soft twist may cause fibre slip and thereby false elongation of the yarn.

(4) That the application of a steady *even* tension to all the threads tested is impossible.

When contraction has been arrived at by this or some other method, the following "loom particulars" can be obtained—

(*a*) Threads per inch in loom, and the reed width, by direct proportion between the *finished* particulars and the *loom* particulars, as influenced by the measured contraction of the weft threads.

(*b*) Similarly the picks per inch in loom, and the length of the grey cloth can be calculated from the contraction of the warp threads. Thus practically all these particulars depend for their verity on the accuracy with which contraction of warp and weft may be measured.

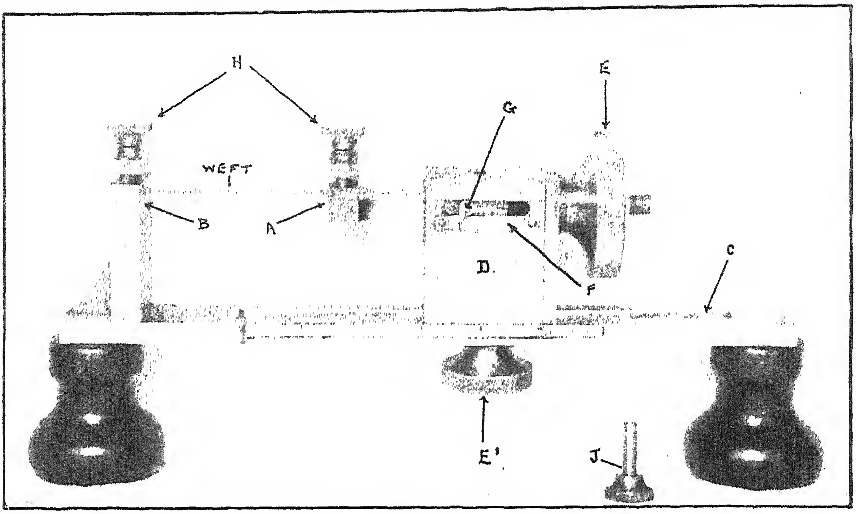

FIG. 1

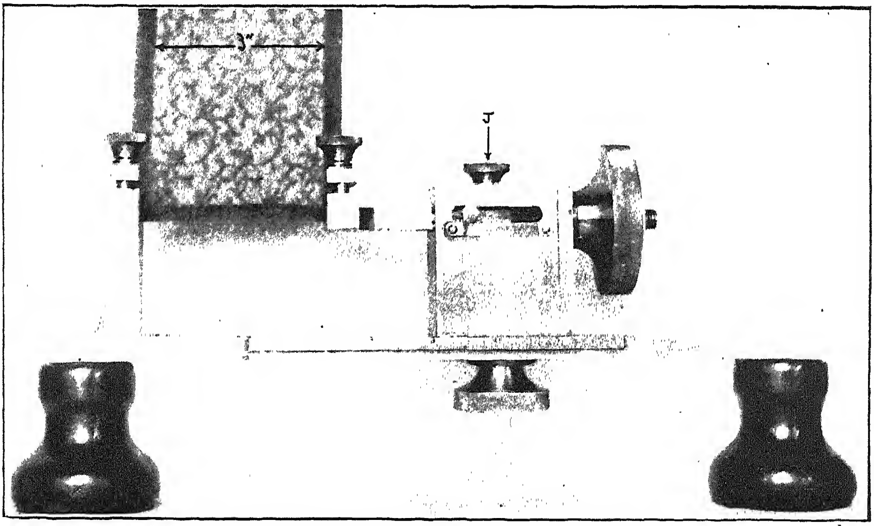

FIG. 2

face page T255

NEW MACHINE FOR MEASURING THE EXTENSION OF YARN

This machine* is constructed with two pairs of jaws—A, movable, and B, fixed (Fig. 2). The fixed jaws B are made rigid at one end of the machine and a fixture with the base C. The latter is a flat, slotted plate of $\frac{3}{8}$ in. material, and is graduated on the edge in inches. Moving along the base-plate is the body of the machine D, containing the travelling jaws A, which slide between two slide bars by the aid of a knurled hand-screw E at the end of the body, this also running in guides. The hand-screw E can be rotated in either direction according to the required movement of the sliding jaws. The body of the machine D can also be locked to the base C by a small hand-screw E^1, thus ensuring that when the machine is set at the beginning of the test no movement of the body is possible.

In the body of the machine is a small slot $\frac{3}{16}$ in. wide × $1\frac{1}{4}$ in. long, which allows for the travel of a small indicator-point G, the latter being fixed to the slide holding the moving jaws and registering any extension of the material on a fine graduated scale F on the side of the machine. The jaws of the machine are of the quick-release type, in order to obviate any possibility of the material fouling the jaws in fixing. Both A and B when released are automatically kept open by means of two small springs which are compressed into recesses when the jaws are closed. The latter are tightened and released by small thumb-screws H, and hold material varying in diameter from $\frac{1}{16}$ to $\frac{1}{1000}$ of an inch without possibility of slipping when tension is applied.

In order to ensure accuracy in the reading of the indicator a locking device consisting of a knurled peg J (Figs. 1 and 2), registers through the top of the body of the machine and through the sliding plate containing the travelling jaws A when the indicator G is at zero. This peg J is kept in position until extension of the material is commenced.

METHOD OF EMPLOYING THE MACHINE

The method of using the machine is believed to be quite different from that employed in connection with other machines for the same purpose. The most important point is that the material, when held by the jaws prior to extension, should be at exactly the normal tension of the threads of the finished cloth. If the threads are first removed from the cloth and then placed in the jaws the tension is disturbed. The use of tension weights ensures similar tension in a series of comparative tests but obviously cannot apply the tension present in the finished fabric. To obviate this the following procedure was adopted—If the size of the pattern permitted it (although any size can be tested) a piece of the material $3\frac{3}{4}$ in. wide was cut. Warp threads were then removed from this sample equally at both sides until exactly 3 in. of cloth remained with a fringe of $\frac{3}{8}$ in. of weft at either edge, as shown in pattern in machine in Fig. 1. The machine was then set to test 3 in. of material by sliding the body along the slotted base until its left edge was exactly over 3 in. on the base scale. In this position there is exactly 3 in. between the inside edges of the two jaws when the indicator G is at zero. The body is then locked to the base by means of the small hand-screw E^1 to obviate any movement. The peg J is also inserted to keep the indicator G at zero. About $\frac{1}{4}$ in. of the fringe of the pattern (pick-wise)

* Provisionally patented.

is then inserted in the fixed jaws B, the latter gripping just up to the edge of the cloth. A similar quantity of weft fringe is then inserted in the movable jaws A, which also grip to the edge of the cloth (Fig. 1). Held *between* the edges of the jaws there is now exactly 3 in. of weft at the tension in the finished cloth, the picks lying side by side exactly as in the fabric. By means of a dissecting needle these weft picks (which may number from, say, 6 to 30, according to the sett of the cloth) are then separated from the intersecting warp threads. No difficulty is experienced with this part of the procedure as a rule, but if milled cloths are being tested, the body of the machine can be moved inwards, *once the jaws are clamped*, to assist in the dissection. When the warp has been drawn away a number of weft picks are left firmly held between the two jaws (see Fig. 2), and when the body of the machine is reset at 3 in. on the base scale (if it has been moved), the tension present in the finished fabric has been restored.

The extension of these weft picks may now be tested. The peg J is removed and the knurled hand-screw rotated in a clock-wise direction, causing the travelling jaws A to move slowly away from the fixed jaws B, the extension being registered by the indicator G. The tension on the material should be tested frequently by lightly tapping with the forefinger until the stage is reached where the tension approximates to that imposed by the temples in the loom during weaving. The extension is then read on the scale. When little or no fibre movement has taken place during finishing, as is the case with cotton, art silk, linen, &c., the proportion between the 3 in. tested and 3 in. plus the extension indicated by the machine, is the proportion between the ends per 1 in. in loom and the ends per 1 in. finished. When fibre movement has taken place due allowance must be made for this as indicated subsequently. The number of threads or picks tested at once is immaterial, single threads or any number can be utilised, but a bulk test is preferable, when the extension indicated is the average of the threads tested. One test only for each fabric is necessary. When testing material, such as rayon, single mohair, single longwool, &c., the extension cannot possibly be ascertained by testing individual threads either by hand or mechanically, as the application of tension causes the fibres to slip and the thread pulls apart, but by testing, say, 20 threads together in the manner indicated, sufficient strength is present in the combined threads to enable an accurate reading to be made.

EXPERIMENTAL

A series of cotton, artificial silk, and angola fabrics were first tested. No fibre movement or shrinkage would be present in these cloths with the result that the readings given by the apparatus should, if accurate, give the actual loom particulars for the fabric concerned. In each case the cloths had been made by the writer so that the loom particulars actually employed were available for the purpose of comparison. The weft was tested in each pattern to arrive at the threads per 1 in. in the reed in preference to testing the warp for the picks per 1 in., as the latter is always liable to variation from the number *intended* to be woven, to that *actually* put into the cloth, owing to the setting-up of the loom and other factors, whereas the threads per 1 in. in the reed are known and cannot vary. A variety of styles was employed in order to test the machine under different conditions. The results were as shown on following page.

Table I.
Cotton, Artificial Silk, and Angola Yarns

Style	Material and Count	Warp or Weft	Ends per Inch Finished	Length Tested	Extension to	Ends per 1 in. in Reed: Actual	Ends per 1 in. in Reed: Calculated
Figd. Lining ...	2/40 Cotton ...	Weft	74	3″	$3\frac{8}{64}$″	72	71·0
Shaded Lining	2/80 Cotton ...	,,	128	3″	$3\frac{7}{32}$″	120	119·3
Whipcord Skirting ...	2/30 Cotton ...	,,	131	3″	$3\frac{18}{32}$″	110	110·3
Figd. Lining ...	120 den. Art. Silk	,,	124	3″	$3\frac{7}{64}$″	120	119·6
Tapestry ...	1/5 Cotton ...	,,	59	3″	$3\frac{1}{8}$″	56	56·6
Poplin ...	2/80 Cotton ...	,,	44	3″	$3\frac{19}{64}$″	40	40·0
Export Dress Fabric ...	2/80 Cotton ...	,,	124	3″	$3\frac{1}{8}$″	120	119·0
Whipcord Suit	19 sks. Angola ...	,,	104	3″	$3\frac{35}{128}$″	96	95·3

It will be seen that the results obtained were strikingly accurate. In each case the "threads per inch finished" was the average of four tests. The extension was read to $\frac{1}{128}$ of an inch where necessary. The machine can, therefore, be relied upon to give *direct* results where no fibre movement has taken place.

The second series of tests was made upon worsted fabrics carrying a "clear" finish. In this case slight fibre movement was anticipated.

Table II.
Worsted Yarns—"Clear Finish"

Style	Material and Count	Warp or Weft	Ends per inch Finished	Length Tested	Extension to	Ends per 1 in. in Reed: Actual	Ends per 1 in. in Reed: Calculated
Whipcord Suit	2/36 Botany ...	Weft	112	3″	$3\frac{65}{128}$″	96	95·8
Tropical Suit ...	2/48 Botany ...	,,	80	3″	$3\frac{17}{32}$″	68	68·0
Tropical Suit ...	2/48 Botany ...	,,	68	3″	$3\frac{14}{32}$″	60	59·3
Twillette ...	2/48 Botany ...	,,	95	$2\frac{1}{2}$″	$2\frac{26}{32}$″	84	84·4
Plain Weave Suit ...	2/48 Botany ...	,,	54	2″	$2\frac{19}{64}$″	48	47·0
2/2 Twill Suit	2/32 Botany ...	,,	70	3″	$3\frac{18}{32}$″	60	59·0

It was found that the fibre movement was not sufficient to affect appreciably the accuracy of the readings. When tension approximating to that present in the loom was applied to the weft, the extension recorded was such that direct loom particulars could be calculated. Botany fabrics were tested in each case, as these were the fabrics where fibre movement was most likely to be present. In the case of cross-bred cloths, the possibility of shrinkage affecting the readings is considerably minimised.

Half-milled, Milled, and Piece-dyed Fabrics

When testing fabrics of these types the fibre movement is sufficient, owing to treatment during finishing, to affect materially the accuracy of the reading supplied by the machine, and due allowance must be made for this factor. The question of such allowance has already had some consideration* and interesting results have been tabulated. In actual mill practice, before measuring the extension of an "unknown" pattern, a "known" fabric similar in quality and, if possible, in structure, could be tested on the machine, and the percentage difference between the reading obtained and the actual loom particulars thus calculated. The "unknown" fabric would then be tested on the machine and a similar percentage allowance made on the reading then given. Accurate loom particulars would thus be obtainable.

The subject is one, however, which affords a large field for further investigation, and the use of an accurate and suitable machine in conjunction with carefully compiled tables showing the percentage allowance to be made on the machine's readings, according to the type of fabric being tested, would result in analysis of an accuracy far in advance of that which now obtains.

The writer wishes to express his sincere appreciation of the assistance and advice rendered him by Mr. R. B. Brigham, of Leeds, in regard to the mechanical details involved.

(British Research Association for the Woollen and Worsted Industries)

SUMMARY

The paper describes a method for the determination of the local variation or irregularity in count of yarns, by weighing successive short lengths on a special balance. The results show up local irregularities, i.e., both thick and thin places are found. The manner in which these occur along the yarn is investigated. The method is now being employed for the determination of irregularity of short lengths of yarn down to and lengths of one inch, spun under various experimental conditions at Torridon, and also for the investigation of the faults occurring in woven fabrics due to the presence of thick and thin places in the yarn. The figures quoted in the paper are illustrative of the method and refer to lengths of 3·14 in. A table is appended showing the average weight of the lengths, the greatest and least weights observed, and the percentage number of pieces of yarn which may come within safe and unsafe limits as regards showing up as faults in the woven fabric, &c.

INTRODUCTION

In Publication No. 52, W. J. Hall[1] has developed a method for the detection and measurement of variations in yarns by weighing hanks taken direct from the cops. Whilst this shows that the variations from cop to cop in all kinds of commercial woollen yarns are surprisingly large, yet for the purpose of weaving it is certain that the variation of the yarn in shorter lengths is as important, since the occurrence and twits, or thick places, will be almost as objectionable in showing up as defects in the cloth, as the variation of count over greater lengths. Local irregularities may also cause trouble in weaving. Oxley[2] devised a method for testing cotton yarns whereby the yarn was drawn between a metal shoe and a flat plate, and the variations recorded optically. In the case of wool, however, it is doubtful if this method would work accurately, as there is a certain amount of compression of the yarn in passing it between the plates. Taking the softness and compressibility of the woollen yarn into consideration, it is obvious that the true variation would be even more difficult to determine by this method than in the case of cotton, since count, twist, and the volume or bulk compressibility would have to be allowed for in such observations.

Another way was therefore sought and it was decided that a weighing method for short lengths of yarn would furnish the information required. In this case (smaller lengths could be taken if required), the weight of individual successive 3·14 in.* over a considerable length of yarn was measured. In order to accomplish this a special form of micro-balance was devised. The form is essentially the same as that used by Barker and King[3] for the estimation of the weight of single fibres of known length, except that the filament is more robust. The diameter of the phosphor bronze filament in the present experiments was 0·004 in. as against 0·001 in. and 0·002 in. in the more delicate apparatus. The balance was thoroughly tested during use for any creep of zero due to incomplete restoration of the filament to its original position due to residual torsion. This was done by observation of the zero after every ten readings had been completed. It was found that this did not furnish any appreciable error. The balance was carefully calibrated before and after each set of 200 readings were taken, and calibration

* This being the circumference of the 1 in. roller used.

curves were drawn from which the weights of the three inch yarn lengths were interpreted directly. These calibration curves showed little difference from each other, but were necessary in order to compensate for any small variations in the instrument due to temperature or other external agencies. They might possibly have been omitted, but for accurate work they formed an effective safeguard. As before, the observations were taken through a telescope placed approximately four feet away from the balance beam. The readings were taken in the humidity room at 70% Relative Humidity (R.H.) and 72° F. The utilisation of the constant humidity and temperature room ensured that the wool remained in the same "condition" (i.e. moisture content), and also eliminated corrections for change in length of the phosphor bronze filament on the balance with temperature variation.

In order to secure successive lengths of 3·14 in., the yarn was wound on an accurately turned roller of diameter 1 in. The roller was fitted with screws at each end which served to hold a metal bar stretching right across the cylinder. This could be tightened on to the cylinder by means of the screws, and it held the yarn in position after winding. Exactly along one edge of this bar a groove was cut in the cylinder. The procedure was as follows. The yarn was wound on to the cylinder and then fixed in position by means of the bar. A sharp knife furnished by a safety razor blade was passed along the edge of the bar, guided by the groove. This cut the yarn into successive equal lengths which hung as a fringe from the roller. By slackening the end screws the bar was slightly loosened, successive lengths of yarn could be taken in order and weighed separately upon the balance. After weighing the yarn on the micro-balance, the lengths were collected in bundles of 100 and these were carefully weighed on an ordinary chemical balance. The sum of the 100 individual weights agreed with the ordinary balance weight of the whole hundred in general to within less than ¼%, so that the error in weight of an individual length was extremely small. Table I. shows typical results.

Table I.

Yarn Firm	No. of Test Lengths Weighed	Total Wt. from separate Micro-balance Readings	Total Wt. from Chemical Balance	Difference Actual	Difference Percentage
B_2	200	1·5044 gms.	1·5045 gms.	+0·0001	0·006%
D	200	2·7993 ,,	2·8049 ,,	+0·0056	0·200%
J_1	1027	13·8490 ,,	13·8853 ,,	+0·0363	0·260%
J_2	200	2·7735 ,,	2·7737 ,,	+0·0002	0·006%

These are typical of the general agreement found throughout.

The yarns selected for test were those used by W. J. Hall.[1] Between the commencement of this work and the completion of the previous work, the yarns had been wound into cheeses from the bobbins, as these had to be returned to the manufacturers from whom the yarns were obtained. This was unfortunate as rendering the results in the two cases not strictly comparable, yet it was felt that the results now obtained could be put forward as—

(*a*) Indicating a new method for the determination of variations in yarns.

(*b*) Furnishing figures which would enable us to develop a method for the presentation of results.

Number of Readings in Italics. **Percentage of Total No. of Readings in Solid Type.**

(*c*) Showing the periodicity, if any, of the variations in the yarn tested.

(*d*) Indicating the method to be employed in testing the regularity of yarns to be produced under either standard or varying conditions in the new carding and spinning plant installed at Torridon.

In the case of yarn J_1, 1,027 tests were made, whilst in the case of the other yarns the number was limited to 600 in each case. As typical of the general character and also to establish the validity of the method, results are given for four separate samples of the yarns tested after conditioning in the humidity room. These are all noted in the tables appended, and for purposes of comparison and identification, Hall's results for these yarns are also included. It will be noted that the co-efficients of variation as given by the short length tests are nearly twice those of the hank tests, and, further, that the determination of local variations places the yarns in a different order in the two cases as regards amount of variability. This is what would be expected since in the hank tests long lengths of yarn are dealt with, and variations from the mean, being both plus and minus, would cancel each other out. The same effect could be obtained by adding together several hundreds of three-inch lengths and comparing the total weights.

Table II. shows the average, greatest and least values, and the percentage difference of the two latter from the average. Details of the origin of the yarn are given. The mean deviations are also stated, as well as the standard deviations, and the co-efficients of variation, both in this case and those determined by W. J. Hall for hank-tests on the same yarns. Below this is a table showing—

(*a*) The number of readings between given percentage limits from the average or mean values for all the observations.

(*b*) The percentage of these numbers of the total number of tests.

(*c*) How many of these readings were above and below the mean.

As already pointed out, it is probable that readings within certain limits, above and below the average, are unimportant to the manufacturer as not affecting weaving or finished appearance in the cloth. The exact fixation of these limits has yet to be determined and, of course, the range would differ according to the uses to which the yarn is to be applied. Careful records are now being maintained, information collected, and experiments conducted with a view to the determination of the limits. In ordinary mathematical work a graph can be used to express the method of variation of a series of results, and it is a combination of a graphical method with what is known in statistics as a "histogram" which may probably be used ultimately.

It may be that for a certain purpose the variation of the yarn, up to say 25%, would not matter. The manufacturer would then only care about—

(1) The mean or average value.

(2) The numbers of extreme values beyond the safety limit, which would be likely to show up as faults in weaving or in the finished cloth.

In the particular case under discussion, thick or thin places would be likely to show up to the detriment of the appearance of the cloth, and it is the number of these thick or thin places that would be the criterion for the

usefulness of the yarn. Thus we see that in the yarns under test, the following number are above 30% thicker than the mean value for the yarn—

Yarn	No. of Tests	No. above 30%	Percentage
B_2	600	0	0
D	600	5	0·83%
J_1	1027	4	0·39%
J_2	600	1	0·17%

It may be that 30% is too high a limit. This is a point to be investigated and inquiries are now being instituted in this direction. If a lower percentage is necessary, Table II. shows the figures required.

Periodicity—A search for periodic occurrences in the yarns yielded interesting results. It may be that on account of some action of the machines a certain fault, e.g. thickening, thinning, extra twist, &c., may occur at definite successive lengths along the yarn. In other words, with the machine working perfectly regularly and repeating its operations in definite order, it will be found doing the same thing at even intervals of time. It can be realised, therefore, that if there is any irregularity in its working there will be a fault or variation created at equal intervals of time, and these faults or variations will be found at equal distances apart along the yarn.

As an example, take the mule draw. Each time the thread is drawn out to the same length and there are the same "take-up" actions, drafting, &c., repeated successively. Now, if there is any variation we would expect it to occur at the same place in each draw if the machine is working evenly. These variations, if they constitute thick and thin places in the yarn, would be detected by the present method. In the case of cotton, Oxley found a maximum thickness at the end of each draw, or approximately 70 in. apart. In later work on woollen yarns, H. M. Williams,[4] of Galashiels, found no evidence of this maximum. The present work, however, points to the existence of such maxima. It is also found that subsidiary maxima occur and analysis of the curves shows that these are quite regular in frequency and point of occurrence.

The detailed examination of this factor is now being pursued. As a preliminary note, however, it may be mentioned that there is one high maximum and two subsidiary maxima in each draw in the particular yarns examined. These apparently occur at intervals of approximately 1/3, 2/3, and at the end of the draw length. They may be due to various causes, and Williams has suggested that the yarn behaves as a string vibrating transversely. Variations may also be due to irregular action of the mule itself or to variations of the condenser, but mere surmise on this point is unwise without further investigation. A detailed and carefully planned set of observations and experiments has now been instituted, and the gravimetric method has been sufficiently justified to warrant its use in the investigation.

My thanks are due to my colleague, Mr. A. W. Stevenson, for the development of the cutting roller. The laborious work of calculation, &c., was done by Mr. E. E. Marshall, Junior Assistant.

Part V.—Some Characteristics of Mohair Kemp.

PART I.—INTRODUCTION

By H. J. W. Bliss, M.A., F.I.C.
(The British Research Association for the Woollen and Worsted Industries)

The circumstances under which this series of papers were collected may be briefly recorded. The staff of this Association had devoted some attention to the possibility of dyeing kemps, chiefly mohair. Howard Priestman had also some years ago, privately, made a special study of certain features of kemp, particularly of some East Indian varieties. Members of the staff of the Animal Breeding Research Department, Edinburgh, with whom the Association is in very close touch, had been studying kemp both from the micrological and the genetical point of view. Then a short time ago Professor Duerden, in South Africa, published an account of kemp in the merino. It was thought therefore that a good purpose would be served by bringing all this information, both old and new, together in an accessible form, more particularly in view of the fact that the text books give but a poor account, and that Priestman's work appears to have escaped notice.

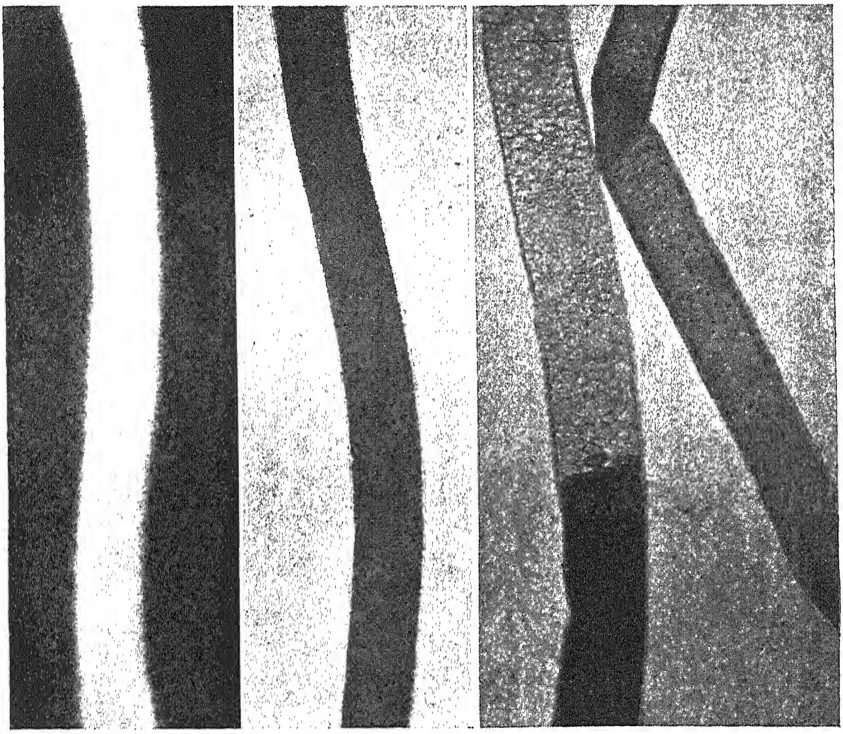
If we turn, for instance, to Matthews' "Textile Fibres" (1924) we find, on the subject of kemp, little but a reference to Bowman's "Structure of the Wool Fibre." Now Bowman seems to have regarded kemp as a malformation of normal wool, which consists in the mildest cases of a fusion of the surface, the disappearance of the projecting scales, and the assumption of an ivory appearance by a short section of the fibre. Such fibres he calls "flat" kemps and he states that they can be dyed with care. In fully-developed kemps, he says that the fibre assumes a much more dense appearance, the "cellular character of the cortical part is entirely obliterated, and the fibre assumes the appearance of an ivory rod without any internal structure being visible." He states that such fibres resist dyeing; that they occur chiefly in certain regions of the body, e.g. on the legs; that they are a sign of want of trueness in breeding; and that they are usually short. His definition therefore comprises first the disappearance of surface markings, secondly the opaque ivory appearance, concealing the internal structure, if any.

Priestman's Work

Priestman (*Yorkshire Observer*, 3rd June and 5th June 1911) went a great deal further, and showed very interesting micro-photographs, some of which are here reproduced with his permission. He showed that the brightness or silveriness of the kemp by reflected light, and its density or opacity by transmitted light, were due to the inclusion of spaces or air bubbles within the fibre, and that if these spaces be filled by soaking in benzene and oil, or by boiling in oil, then the fibre becomes transparent. He disagreed with Bowman's statement that the scales of kemp are fused or non-existent, but declared that under proper conditions (filling the spaces

with a liquid and viewing by transmitted light) they are quite visible. He thought that there may be some cementing substance partly filling their interstices.

An important point is that both Bowman and Priestman seem to have regarded kemp as a faulty wool fibre, and that perhaps sufficient distinction was not drawn between "true" short kemp and kempy or medullated wool.



PART I.—FIGS. 1, 2, and 3 (Priestman)

FIG. 1—Kemp illuminated by direct sunlight.
,, 2—The same kemp illuminated by transmitted light, opaque except at edge.
,, 3—Opaque kemp steeped in benzene until portions are quite transparent.
Taken from same sample as Fig. 2, and with same magnification.

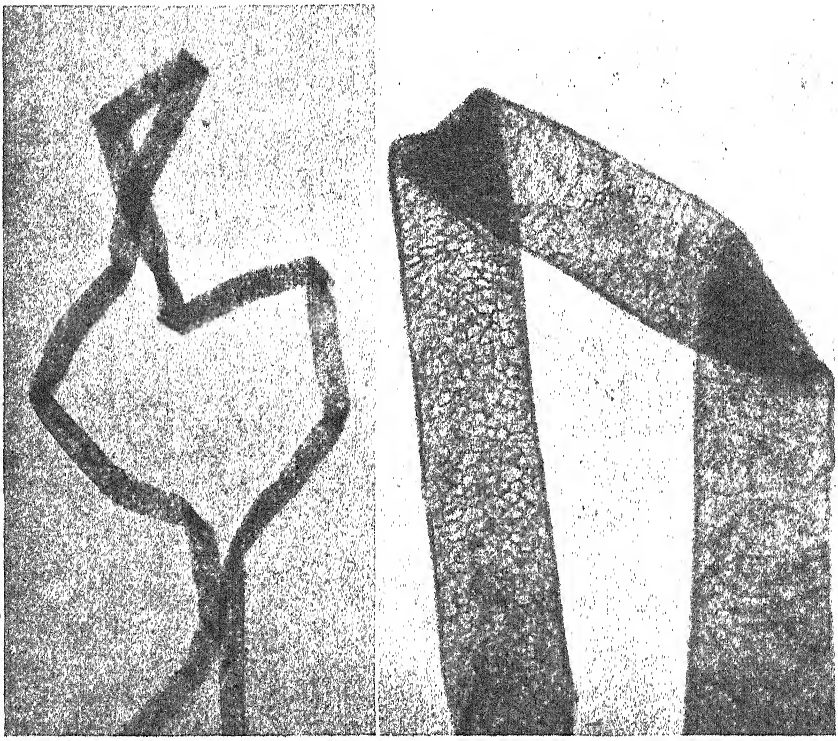
Flat Kemp

Bowman (1908 ed.) refers to "flat" kemp, but a study of his actual words seems to show that he examined incomplete or partial kemps which had a normal (medullated) internal kemp structure. Such kemps can be dyed "with care." Priestman, on the other hand, found a different type of kemp, which fully deserves the name "flat." He first observed these kemps in patterns of cloth submitted for diagnosis, but could not state whence they had come. Later, after a prolonged search among different types of wool, he found this type in certain East Indian wools. Since these kemps do not appear to have been generally recognised, his description is worth quoting somewhat fully.

"Under certain circumstances they will not show in the cloth. On the other hand, they often do show very badly, even when they are thoroughly dyed, simply because they are flat and therefore reflect a great deal of light

when it strikes them at the necessary angle. They show just as an ebony paper knife would show if laid amongst a lot of black pencils. Each pencil reflects a line of light from its curved surface. The paper knife reflects a sheet of light from its whole width.

"In dyed and finished cloth flat kemps generally appear on the surface in a way that makes even competent manufacturers regard them as hemp



PART I.—FIGS. 4, 5 (Priestman)
FIG. 4—Flat kemp like "empty hose-pipe." ×30.
,, 5—Portion of flat kemp. ×80.

or grass. They appear lighter than the rest of the fibres in the pieces, but under the microscope there is little difference in depth of colour. The apparent lightness is due to reflection. Under the microscope they resemble nothing so much as a woven canvas hosepipe which is empty and therefore flat. Their shape prevents all waviness in a horizontal plane, and if they are bent they act exactly as a tape or an empty hosepipe would do, turning over and forming an angle at each bend. In this, of course, they differ entirely from normal wool fibres or from ordinary kemps. It is probably their erratic shape which deceives so many practical men, and were it not for the very obvious way in which the scales show under the microscope it would be extremely hard to identify them as wool at all."

These kemps were uncommon, but occurred from time to time in low serges. They showed most in browns, olives, and greens, were almost invisible "in the grey," i.e. undyed, and were well concealed in navy blues and blacks. Certain kinds of black dyes seemed to swell these fibres up to a nearly round section again.

After a considerable search he found these kemps in an East Indian wool, and their properties were investigated. It was found that they contained air. He suggested that the internal cells of the fibre had contracted greatly (thus admitting air), but had not entirely disappeared, since black dyes again filled out the fibre, which pointed to the presence of some material upon which it could act.

Flat kemps were also observed to float in water (unless boiled to displace the air), while ordinary kemp sank.

Structure of Kemp

Priestman also observed and photographed very clearly the characteristic round or square cells of the kemp medulla (both ordinary and flat), and advanced a theory that these round cells are due to an abnormality in the hair root, which produces these in place of the normal spindle-shaped cells.

Later knowledge (see the following papers) shows that the medulla of true kemp is the product of a special group of cells in the root, and also that it is of annual growth, and a survival of the outer coat of the wild sheep. It is, therefore, scarcely an abnormality.

It seems that there is scope for further study of the medulla, both from the histological and physiological aspects. We have "true" kemp, but we also have partially kempy fibres; we have young animals producing clear wool or hair, and the same animals yielding white (i.e. medullated, air-containing) hair later in life; and we have some that habitually produce partial or discontinuous medulla. If the medulla is of a distinct cellular origin in the skin, and if it is sometimes developed and sometimes suppressed, it is perhaps conceivable that the factors governing its development might be elucidated. The derivation of true kemp from the ancestral outer coat does not seem to cover the whole field.

The Air in Kemp

It is of interest to note that Barker and King, of this Association (*J. Text. Inst.*, 1926, **17**, T53), have recently published work on the specific gravity of wool which gives an indication of the actual air content of the medulla in kemp or kempy wools. Work now in progress also indicates that there is probably some chemical difference between kemp and normal fibre.

PART II.—KEMP FIBRES IN THE MERINO

By Professor J. E. Duerden, M.Sc., Ph.D.
(Rhodes University College, Grahamstown, South Africa*)

In South Africa kemp is known as a straight, coarse, dull, opaque white fibre, found in greater or less numbers mixed with wool. It is rather brittle and non-elastic, and in the process of manufacture does not show the dye like true wool fibres. It is a source of deep concern to the farmer, owing to the depreciation which it causes in the value of the clip, and to the manufacturer from the lack of uniformity in texture and colour which it confers on the finished article.

Practically all merinos show a certain amount of kemp at one period or another. Fibres can usually be found on the head and over the bare patches of the inner side of the legs, while in some sheep they are more or less distributed throughout the fleece. They are easily recognised on account of their coarse, straight, white appearance, and stand out conspicuously against the true wool, the fibres of which are much finer, crimped, and closely arranged in staples. Again, while kemp may be plentiful in certain parts, the fibres are always single and isolated, never in staples, and are intermingled with the denser growth of the wool. Usually they are not more than an inch or two in length and oval in section, not circular like wool fibres. On the face and legs they are always to be found in position, growing from the follicles, but in the fleece they often occur loose, having been shed from the follicles and remained entangled in the staples.

Microscopic Appearance

Examined under the microscope by transmitted light, a ripe kemp fibre has the appearance represented in Fig. 1. At the base it is slightly swollen and frayed out into a number of short delicate fibrils. This represents the root of the hair which has completed its growth, and is ready to be pushed out, or is already shed. Above the root is a clear, transparent part, and beyond this is a black, central core surrounded by a clear margin, and extending nearly the full length of the fibre. For a variable distance towards the tip the fibre is again clear and solid, terminating in a sharp point, as in all hair and wool fibres which have never been clipped. If the same fibre be viewed under the microscope by reflected light on a dark background, the central core, which was black in transmitted light, appears as a silvery white streak down the middle.

Under a high power of the microscope the clear parts towards the root and tip are found to be uniform in structure throughout their thickness. Like true wool the fibre here consists only of solid, fusiform, cortical cells, and an outer serrated cuticle, whereas the remainder of the fibre has an additional thick central core or medulla, occupied by minute air inclusions (Figs. 2 and 3). It is the presence of the medulla which gives kemp its peculiar characteristics as distinguished from wool. Around the core, however, is a clear marginal cortex with a superficial serrated cuticle, just as in wool. The blackness of the core seen by transmitted light is due to refraction of the light by the minute inclusions of air within the interstices, and the silvery whiteness on a dark background to reflection of the light from the surface of the inclusions.

---

* A more detailed account appears in Duerden and Ritchie, "Kemp Fibres in the Merino Sheep," Science Bulletin No. 34, Dept. Agric., Union of South Africa, 1924.

PART II., PLATE I.

FIG. 1—Kemp fibre from merino lamb, showing medulla.
,, 2—Root of kemp fibre, magnified, showing air inclusions in medulla.
,, 3—Tip of kemp fibre, magnified, showing air inclusions.
4—Medulla of kemp fibre with air removed.

Air in Kemp

All kemp fibres contain the central core of air within the minute hollow spaces in the medulla, and this gives them their peculiar dull whiteness when seen in contrast with wool fibres which are translucent. The air can be removed by placing the fibres for a short time in strong alcohol, and the fibres are then clear in transmitted light and no longer silvery by reflected light. In addition, the medulla is seen to possess a structure altogether different from the rest of the fibre, the cells of which it is composed being cubical and hollow, with thickened spinous walls (Figs. 4 and 5). As the alcohol evaporates air again enters the medullary spaces, and the black opacity and silvery whiteness are restored.

In the early development of a kemp fibre the medulla is found to arise as a special group of cells in the middle of the shaft, derived from the basal layer of the epidermis (Fig. 6). In the case of the cuticle and cortex keratinisation is complete, and the cells become solid, while in the medulla the cell walls only are thickened with minute spinous projections, the cavity remaining in each cell becoming full of air as the cytoplasm disappears. Wool fibres on the other hand are constituted entirely of solid, fusiform, cortical cells, covered with a serrated cuticle, the hollow medullary cells and air inclusions being absent. Wool allows light to pass through as well as to be reflected from its surface, whereas kemp is opaque at the core and reflects white light only. The fusiform cells of the cortex confer a certain degree of elasticity upon the wool fibre, while the medullary cells of kemp are non-elastic. Further, under ordinary conditions, where the merino is shorn, wool fibres grow continuously year by year without ever being shed; but kemp fibres have only a limited growth and, being shed from time to time, may often be found loose and entangled in the fleece.

It must be understood there are all stages in the formation of a medulla, and consequently all degrees of kempiness. Some fibres have only a very fine core with very few air inclusions; the latter may be even detached from one another, showing what is known as a "broken medulla." In general it will be found that the coarser is the fibre, the thicker is the medulla and the denser the air inclusions. For the sake of uniformity in terminology, it is suggested that any fibre containing air should be classed as kemp, or at any rate as kempy. The term would then include such coarse fibres as are known as dog-hair and gare, and even some of the stronger English wools where considerable air is present in the medulla. No sharp definition can be given of hair as contrasted with kemp or wool, but the fibres are usually coarser and medullated like kemp, and unlike wool.

Dyeing of Kemp

The view is generally held that kemp fibres do not dye, and on this account alone it is very objectionable among wool, since it interferes with the uniformity of colour of the finished product. Experiments prove, however, that the various dyes penetrate kemp just as readily as they do wool. This can be easily seen when the medullary air is removed; the cuticular, cortical, and medullary cells are then coloured alike, all being formed of the same chemical substance, keratin. When air inclusions are present, however, the colour of the dye is not transmitted, since the fibres are rendered opaque by the air. It is not that the fibres do not take the dye, but the physical conditions induced by the presence of fine inclusions of air prevent the colour showing to perfection.

Manifestly one of the great objections of the manufacturer to kemp, and to all fibres containing air inclusions, would be overcome if at some stage during the process of dyeing the air could be permanently removed. This might be done either by exhaustion or by solution in some reagent

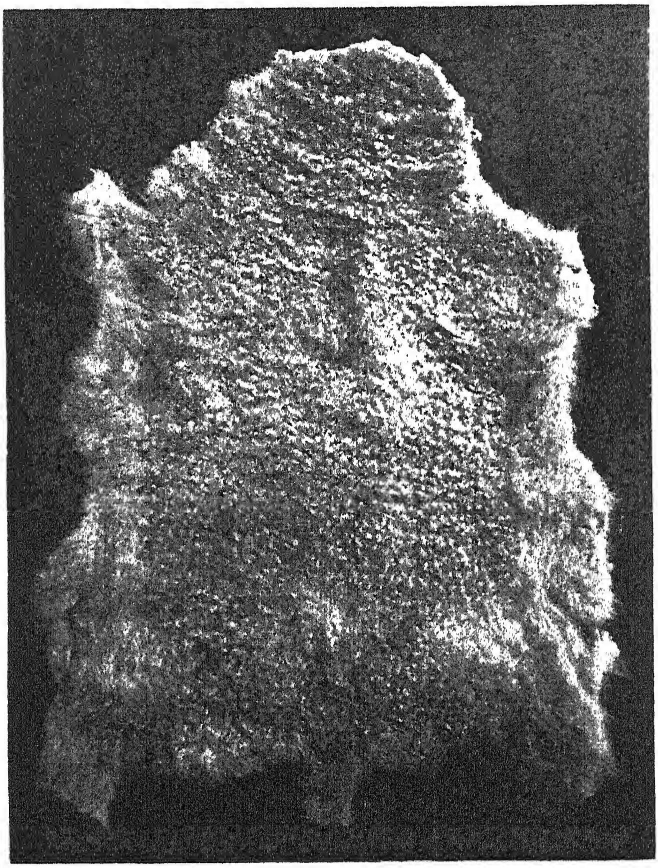
such as alcohol. It is plain that where the highest perfection of colour is desired, the fibres must on no account contain medullary air.

Origin of Kemp

A true understanding of the origin of kemp can be gained only from a comparison of the outer covering of the merino with that of other breeds of sheep and goats, and with mammals generally. In their natural state nearly all mammals have two coats of hair—an outer coat of long, coarse fibres, and an under one of short, soft, fine fibres, the latter constituting the true fur in fur-bearing animals. The outer coat serves more for protection, the under one for warmth, and both tend to vary with the season.

In the merino, therefore, we have to consider the possible occurrence of these two coats. All considerations of its ancestry go to prove that the merino had originally an outer coat of coarse, kempy fibres, and an under one of fine fibres. In the best strains the kempy coat has now largely disappeared from the adult as a result of long selective breeding, while the woolly coat has been almost exclusively developed, and to-day forms



PART II., PLATE III.

FIG. 7—Skin of new-born merino lamb. The outer coat of long kempy fibres is clearly shown at the sides, and the under coat of curly tufts of wool over the general surface.

practically the only covering of the sheep. When kempy fibres occur they may be looked upon as the retention of an ancestral hereditary character which has not yet been bred out. Under farming conditions the fine fibres have increased greatly in number and crimpiness, and instead of being shed at intervals now grow continuously for the lifetime of the sheep, and exceed the kempy fibres in length.

That the ancestors of the merino had two coats—a longer coarse and a shorter fine—receives striking confirmation from the covering of the new-born lamb (Fig. 7). Here the whole of the body, the back and sides, as well as the head, limbs, and tail, is provided with long, straight, kempy hairs,

each with a medulla and air inclusions, while below is a denser covering of fine solid fibres, arranged in short, curly tufts. Different lambs vary much in the number of the outer fibres, and they may be almost absent from some parts of the body and plentiful in others. The coarse hairs are shed very early from the time of birth onwards, and the covering then consists of the under coat only, the woolly fleece. Sections through the skin of the new-born lamb show all stages in the shedding of the coarse fibres.* The well-known principle embodied in the biological Law of Recapitulation implies that in the course of their development animals tend to pass through the stages which repeat the characteristics of their ancestors. Accepting this, we may with every justification regard the two coats of the lamb as an ancestral stage in the evolution of the merino. As a result of selection under domestication, the kempy coat now largely disappears after birth, to reappear, however, with each succeeding generation of lambs. Remnants tend to persist longest on the extremities—head, legs, and tail—but complete elimination should be possible by continued selection in breeding.

PART III.—KEMP IN THE FLEECE OF THE WELSH MOUNTAIN SHEEP

By J. A. Fraser Roberts, M.A., B.Sc.

(Animal Breeding Research Department, University of Edinburgh)

INTRODUCTION

The following account of kemp in the fleece of the Welsh mountain sheep has been prepared from some of the results of work in connection with a scheme for the investigation of the possibilities of wool improvement in that breed put forward by the University College of North Wales, Bangor, and carried out in conjunction with the Animal Breeding Research Department, University of Edinburgh.

The scheme aims at improvement by selection within the breed, and it will readily be appreciated that this fact has led to the problems connected with the occurrence of kemp being approached from a particular angle—and an essentially practical one. There is extreme variation in Welsh fleeces, and the first consideration is to discover and measure those differences which make a fleece a good one or a bad one, and so attempt to increase the number of the former class at the expense of the latter. For this purpose, those characters that are common to all Welsh sheep—good and bad alike—for example, the nature of the covering of short hair on the face and legs, are only of incidental importance at present. It was urgently necessary to find a definition for kemp that would be sound economically and at the same time rest upon real biological distinctions between kemp and other fibres. It was no less urgently necessary to develop a method for the quantitative estimation of kemp, so that the great individual variations in this respect could be expressed in actual figures. Having once reached this point, it becomes possible to consider the extremely important subject of the occurrence of kemp, together with all those other technical, scientific, and agricultural factors that are involved in such a scheme. It will be found that little stress has been laid on microscopic analysis; the work is less a study of kemp as such than an elaboration of methods for a particular purpose, and it was found that this object could best be attained in other ways. It is hoped that the methods developed for the study of Welsh wool will be of use in the study of the fleeces of other breeds. These methods are being utilised in this way in this Department.

The laboratory work in connection with this research has been carried out at the Animal Breeding Research Department, University of Edinburgh, and I wish, as always, to express my gratitude to my chief, Dr. F. A. E. Crew. Material has been obtained at the College Farm of the University College of North Wales, the pedigree and mountain flocks of the College being freely utilised. Professor R. G. White, in addition to making the work possible, has devoted to it a great deal of personal attention, and it would be impossible to over-emphasise the value of his co-operation. My thanks are also due to Mr. R. N. Jones for his help in the practical grading of the sheep, and to Mr. James Briggs, of Elland, for assistance on the technical side. During the course of the work close contact has been maintained with the staff of the British Research Association for the Woollen and Worsted Industries; their assistance has been of the greatest value.

The Macroscopic* Characteristics of Kemp

If a sample of Welsh wool is examined it is usually apparent that there are present fibres having certain peculiar characteristics that mark them off from ordinary wool fibres. They are called kemp, and it is the purpose of the first part of this paper to consider these fibres from various points of view and so arrive at a satisfactory definition. Several salient points stand out on naked eye inspection. Plates I. and II. show four samples of wool containing varying amounts of kemp. Plate III. shows a range of kemps slightly magnified. Plate VII. A is a very kempy sample, while VII. B shows the same sample separated into kemp and non-kempy fibres. Reference to these photographs will make the description clear.

(1) *Shortness*—Kemps are short in comparison with other fibres, varying from $\frac{1}{4}$ in. to 2 in. or a little more in length; those approaching the latter limit are rare.

(2) *Coarseness*—On the average they are extremely coarse.

(3) *Waviness*—The great majority exhibit a characteristic waviness which is well shown in the photographs.

(4) *Whiteness*—Kemp fibres stand out owing to a dead-white opaqueness which contrasts sharply with the more transparent appearance of other fibres. This is due to their relatively large medulla, the meshes of which contain air, hence light is refracted.

(5) *"Breaks"*—Certain kemp fibres exhibit at points along their length more transparent flattened deformed portions. In addition, there are sharp bends at different points along the fibre.

(6) *Flattening*—It is apparent that kemps are usually not nearly circular in section.

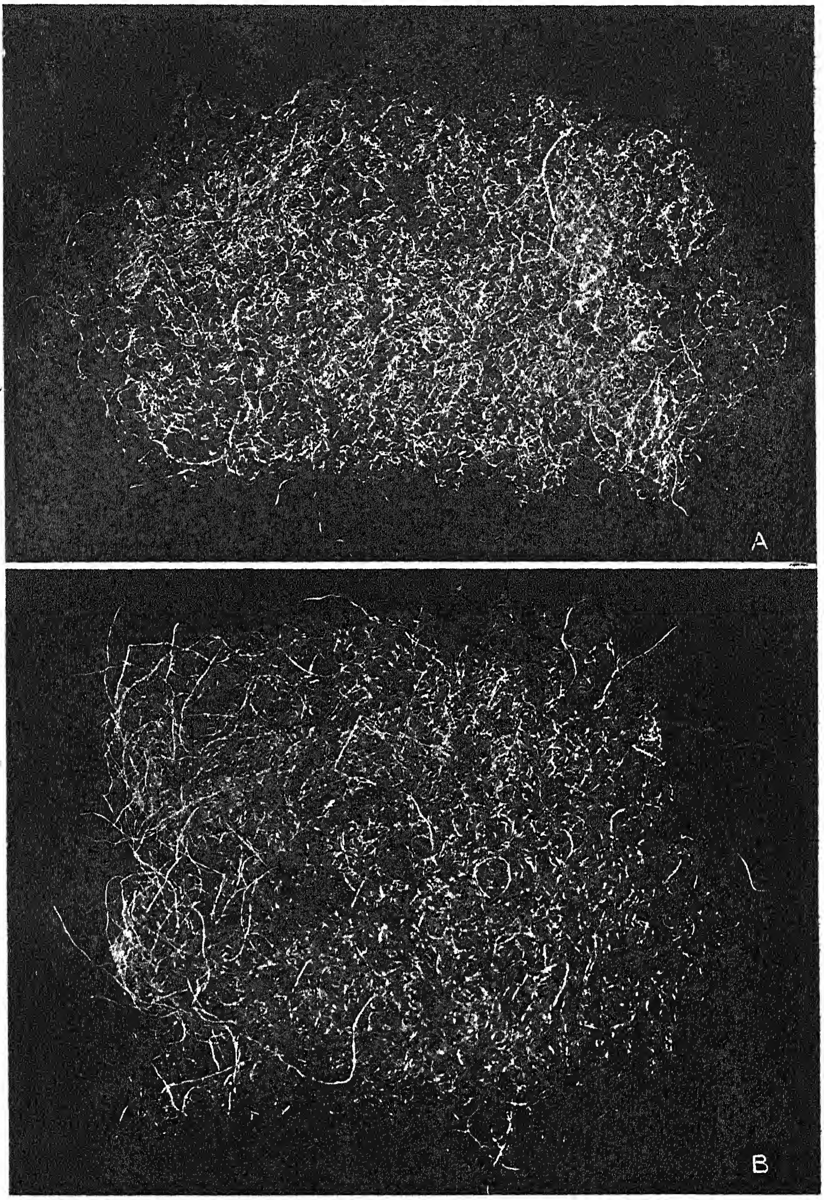
(7) *Brittleness*—Their tensile strength is very low.

(8) *Pigmentation*—In Welsh fleeces, "red kemp" sometimes occurs. These fibres are kemp fibres and it is very characteristic of kemp that it should sometimes be pigmented if there is a tendency in this direction, while the other fibres are not coloured or at least only occasionally show lightly pigmented tips.

(9) *The Nature of the Extremities of Kemp Fibres*—None of the above points are absolutely diagnostic of kemp. They are certainly true in most cases, but individual fibres may be found where one or more do not hold. Some of the points are relative and other fibres may occasionally approach kemp in regard to some of them. What the writer believes to be the most important characteristic of kemp from the point of view of definition remains to be discussed. Almost every kemp fibre will be found to possess a whip-lash tip, and towards the proximal† end there is a thinning off which terminates in a little bulb which indicates that the fibre has been shed from its follicle. In the case of those kemp fibres (relatively few in number) that do not show this characteristic it is readily seen either that the fibre has not finished its growth and has been cut off in the middle, or else that the tip has been broken off, but this is rare. This characteristic involves the mode of growth of kemp fibres and is discussed more fully in the next section.

In some samples fibres are occasionally found which appear to possess portions having some of the characteristics of kemp, the remainder of the fibre being definitely non-kempy. Such fibres are not common and their kempy portions hardly ever resemble typical kemps. It is rather the thoroughly a-typical finer kemps that they do resemble. For many reasons

* i.e. Naked eye. † i.e. Nearest the body.



PART III., PLATE II.

A—Sample of Welsh wool (shoulder), containing 1·8% kemp by weight. $\times 1\frac{1}{2}$.
B—Sample of Welsh wool (rump), containing 8·0% kemp by weight. $\times 1\frac{1}{2}$.

they cannot be admitted to be true kemp fibres. They are referred to below in connection with the question of definition.

The Growth of Kemp

If the coat of a Welsh sheep is examined, say, in December, it will be found that the kemp fibres are either lying free in the fleece or else are very loosely attached to the skin. All will show both root and tip. In the case of the other fibres composing the fleece, wool or hair as the case may be, the vast majority will show neither of these features. Kemp is therefore annual in its growth and the examination of fleeces at different times of the year shows that the growth period is roughly from March to September or October. Fibres other than kemp grow continuously, merely becoming thinner at the time of the "rise" in the wool. Of course, fibres other than kemp are occasionally shed and new growth does occur, but such cases are relatively infrequent and represent a very different phenomenon to the regular annual growth of kemp. Here there is to be found a real fundamental distinction between kemp and all other fibres.

The mode of growth of kemp is well illustrated by Plate IV. A. In this case the kemp is red and so shows up clearly against the white wool. It will be seen that towards the tip of the staple lies the previous year's growth. There is then an interval and then the new year's growth which was coming up when the sheep was shorn. Plate IV. B shows a sample of Suffolk wool containing dark fibres which are also of a kempy nature, and in this case, too, the same phenomenon is seen.

It should be noted as a very important distinction that the shedding of kemp and the appearance of the new crop in no way corresponds in time to the "rise" in the wool, a time when some other fibres instead of merely becoming thinner are occasionally shed and replaced by new ones. By the time the "rise" occurs the growth of the kemp is already well established.

The Microscopic Characteristics of Kemp

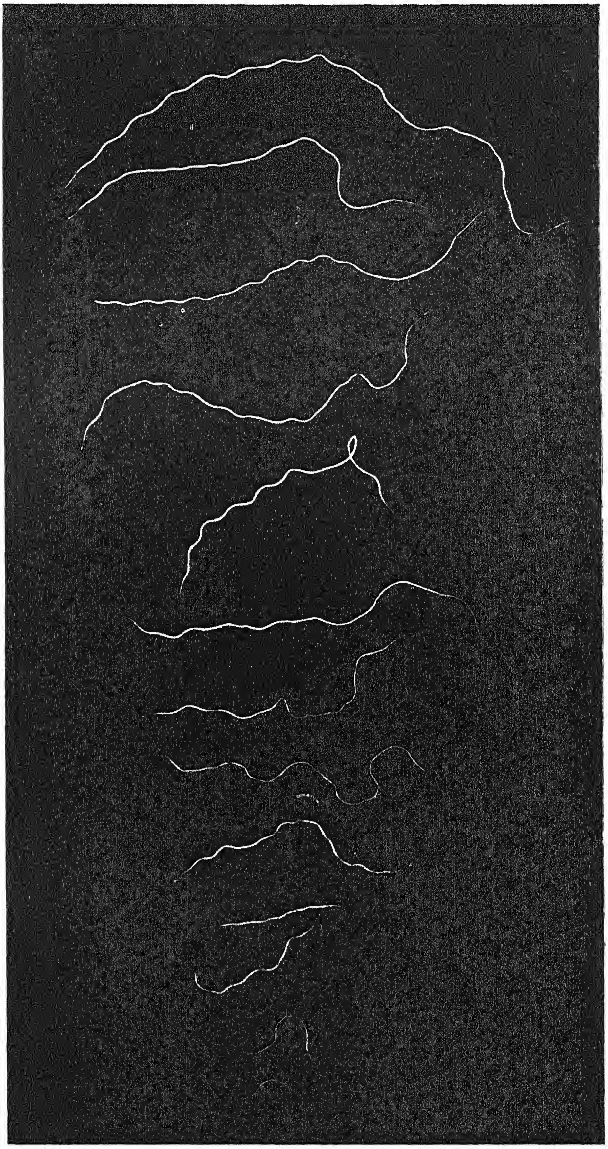
Plate V., Figs. 3–6, show sections of kemp fibres. Fig. 7 is a low-power picture of the proximal end of a kemp fibre. Figs. 1–2 are sections of hair from the Welsh fleece for comparison. A histological study shows that kemp fibres, like other mammalian hairs, are made up of three layers—cuticle, cortex, and medulla. The cuticle possesses some special features as compared with that of ordinary hair fibres from the Welsh fleece, in that the scales are more compressed in a vertical direction; this gives the fibres a more serrated edge in section. The cortex for the greater part of its length is relatively thin, the greater part of the bulk being taken up by a reticulate medulla. The medulla of kemp fibres is rather less regular than that of hair fibres, being less evenly rounded and appearing more compressed.

A special feature of kemp is the extreme irregularity of shape at various points. This is well shown by the photographs. Fig. 4 shows the medulla compressed almost into a state of solidity.

The Origin of Kemp

Most mammals possess two coats—an outer coat of protective hair, and an inner warmth-retaining coat of fine hair; this is also true in the case of many wild and primitive varieties of sheep which undoubtedly resemble the ancestors of our modern breeds. There are several reasons for holding that kemp in the modern fleece is a remnant of the primitive outer coat—

(1) There is great similarity between kemp fibres and primitive hair; Plate VI., Fig. A, shows a sample of the coat of *Ovis dalli*, the American



PART III., PLATE III.

Various types of kemp fibres from Welsh fleeces. $\times 1\frac{1}{2}$. Note extremities.

Bighorn, and Fig. B on the same plate is a photograph of a very kempy piece of Welsh wool taken from the hind leg just above the hock. The similarity is very marked.

(2) Certain sheep may be found the coats of which represent a sort of intermediate condition between the two coats of the primitive sheep and a kempy fleece. It is stated, for example, that Shetland sheep can be found in which there are practically two coats, and yet this condition would be only a little more extreme than, say, a very kempy Welsh fleece.

(3) In many primitive varieties of sheep the outer coat is pigmented and the inner coat is white except that some of the fine wool fibres have slightly pigmented tips. Exactly the same situation is seen in Plate IV., Fig. A, a sample of Welsh wool showing a lot of red kemp. Where red kemp occurs it is usual to find a few wool fibres with lightly pigmented tips. The same phenomenon is even better seen in the Suffolk; for this description and for the photograph on Plate IV., Fig. B, I am indebted to my colleague Mr. J. E. Nichols. In the Suffolk fleece, when dark fibres occur, the pigmentation is found in short, very dark, definitely kempy fibres, and in addition many of the wool fibres have lightly pigmented tips.

(4) The writer has not had much opportunity of observing the mode of growth of the coat of primitive sheep. In this Department, however, there is at present a black-headed Persian ewe, a gift from the South African Government. This sheep possesses a coat which is strictly analogous to that of wild sheep. It consists of a very coarse outer coat and an extremely fine inner coat. Many of the fibres composing the outer coat were (end of October 1925) quite loose and came away readily, showing the proximal thinning and the little bulb so typical of Welsh kemp, and that was the very time of the year that the precisely similar process of the shedding of kemp was going on in the fleeces of Welsh sheep.

The Definition of Kemp

A consideration of the above facts leads naturally to a definition of kemp. An adequate definition should satisfy the following conditions—

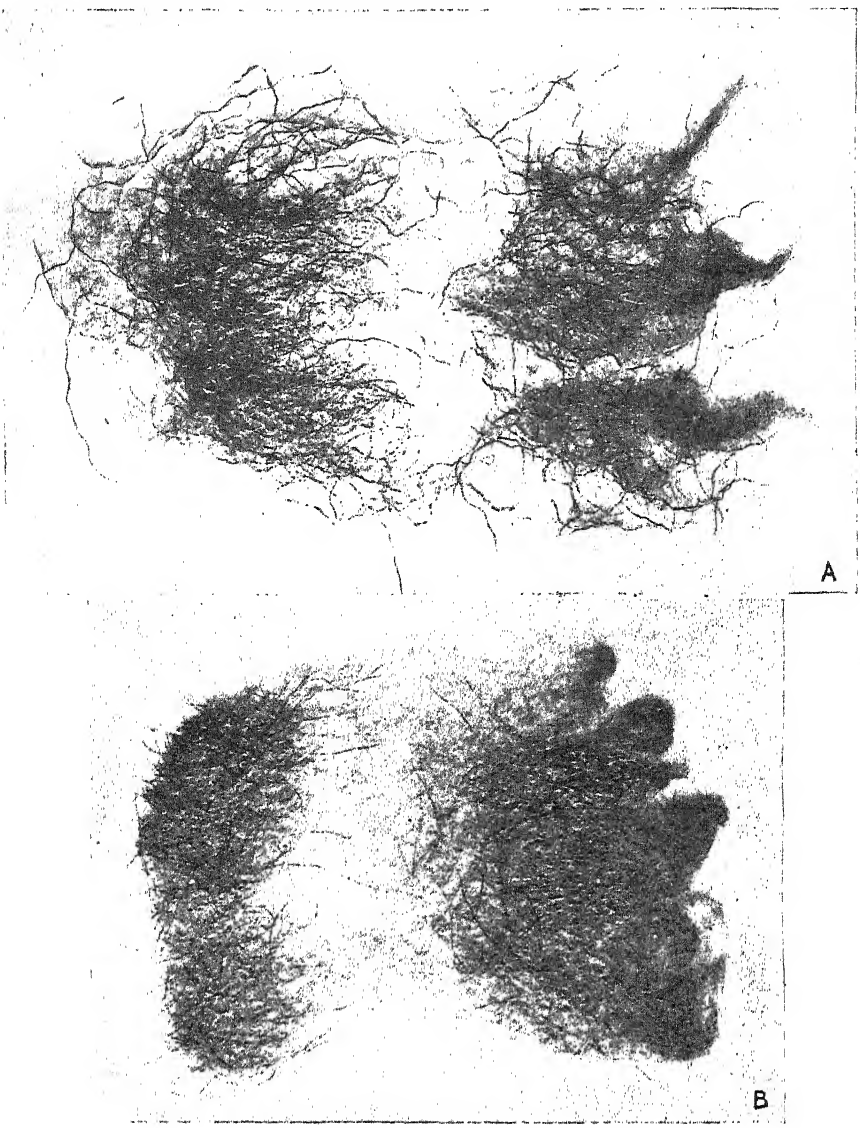
(1) The distinction between kemp and other fibres should be both sharp and qualitative.

(2) The distinction, if it is to be used practically, should permit rapid and accurate naked-eye separation into the two groups—kempy and non-kempy.

(3) It is desirable that the separation into the two groups should be one that would correspond to the technical opinion of what constitutes kemp.

(4) It would be highly satisfactory and an indication of profitable biological discovery in the future if the definition were to represent a real morphological distinction.

Above all, then, kemp is a fibre that is annual in its growth. This distinction satisfies conditions 1, 2, and 4, and it will be shown later how well it also satisfies condition 3. In an attempt completely to separate the kemp fibres from Welsh samples, this characteristic, together with a recognition of those qualities mentioned under the heading "macroscopic characteristics,"



PART III., PLATE IV.

A—Sample of Welsh wool containing red kemp to illustrate mode of growth of kemp fibres. Natural size.

B—Sample of Suffolk wool containing black kemp fibres to illustrate mode of growth. Natural size.

are amply sufficient. In a sample taken at shearing time nearly all the kemps will have root and tip and present no difficulty. At the bottom of the staple will be found a certain number of cut kemps, and these can in almost every case be recognised by attention to the points mentioned.

In some samples the anomalous fibres already described will be found; they appear to be wool fibres for the greater part of their length, but exhibit portions (usually tip) of a kemp-like nature. It is impossible to admit them as kemps, although to the manufacturer they would be equally objectionable. They can be neglected for the purpose of definition and estimation for the following reasons—

(1) The number found is always extremely small compared with that of the regular kemp fibres. In many samples none occur.
(2) Although they exhibit "kempy" portions these portions are hardly ever quite the same as typical kemp; it is rather the finer a-typical kemps that they resemble.

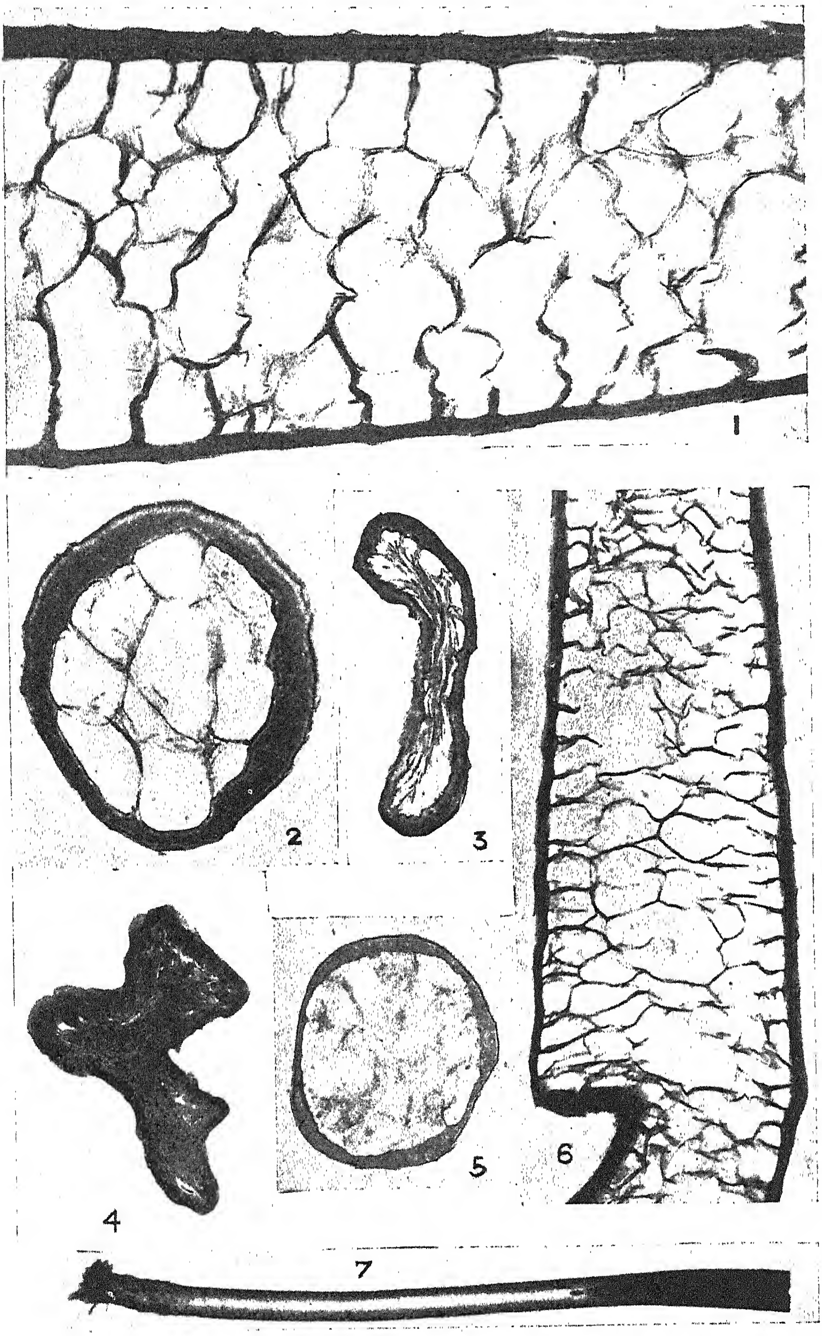
It is possible that some observers would call "kempy" any fibre which showed by its coarseness and opaqueness that it had an air-filled medulla. Hair fibres and many quite fine wool fibres have an air-filled medulla at least for part of their length, but such fibres shade off without definite discontinuity anywhere from coarse hair to fine wool, so that such an attitude would destroy the most useful distinction that can be made out in the fleece. There are many important qualities in the fleece, and fineness of fibre is not the least of them, but though an important subject it is quite a different one. The problem of kemp involves the elimination of a totally distinct coat of the sheep and is therefore a simpler one in every way.

The hypothesis as to the origin of kemp is well supported but is, of course, hypothesis and not fact; nevertheless it is an encouraging speculation in that it emphasises the fundamental nature of the distinction which has been reached independently by direct observation.

The Quantitative Estimation of Kemp

The preceding part of this paper leads to an examination of the question of the estimation of kemp by the actual separation of fibres in samples. Methods which involve the counting of fibres are not very satisfactory; they are too laborious and present several difficulties, e.g. cut and broken fibres. The method which has been found to give by far the best results is the determination of the weight of kemp in a sample. From 0·2 to 0·3 grams of wool are carefully separated off so as to get a complete staple and washed in ether. The sample is then dissected out bit by bit on a board covered with black velvet, the kemps being separated from the non-kemp fibres. The two portions are then weighed and the percentage kemp by weight in the sample determined. After considerable experience of this method the writer finds that there is no difficulty about the separation and that a very accurate determination can be made.

The chief difficulty is the selection of samples which shall give a fair estimate of the kempiness of the fleece as a whole. Not sufficient work has yet been carried out for an authoritative and final opinion to be pronounced on the subject. It is a matter of the careful selection and analysis of samples from various regions in the case of a large number of fleeces, and a determination of the regularity of the distribution of fibres over small areas; this work is now in progress.



PART III., PLATE V.

FIGS 1 and 2—Longitudinal and transverse sections of hair from Welsh fleece (for comparison). ×425.

,, 3, 4, 5, and 6—Longitudinal and transverse sections of kemp fibres. Figs 3 and 4. ×250. Figs. 5 and 6. ×220.

FIG. 7—Proximal end of kemp fibre. ×55.

Although the question of the precise method of sampling has yet to be standardised, some indication of the results obtained may be of interest. Most of the analyses so far carried out have been on samples taken from the point of the shoulder and the point of the rump in the case of each sheep (sometimes the britch instead of the point of the rump). These two figures appear to give a very fair indication of the kempiness of the fleece as a whole. The point of the rump is about the worst place in the fleece apart from the trimmings, and if kemp is low in amount there the fleece may safely be pronounced relatively free from kemp. The percentage at the shoulder is of importance because it gives an indication of the extent to which the kemp is spread throughout the whole fleece; 2% or 3% of kemp at the shoulder is a serious matter and is a certain indication of a fleece that is thoroughly kempy all over.

Plates I. and II. show four samples of Welsh wool—two from the shoulder and two from the rump—containing varying amounts of kemp. Plate VII. shows a piece of the same sample as Plate I. A, and below the same sample separated out. In this case the proportion of kemp was 16%. Welsh fleeces can be found with less than 0·1% both at shoulder and rump; in the case of really kempy fleeces these figures may go up to 7% and 20–25% respectively. A very fair estimate of the kempiness of the fleeces is therefore possible on the basis of these figures. In the next section some typical analyses are given and compared with the manufacturer's grading.

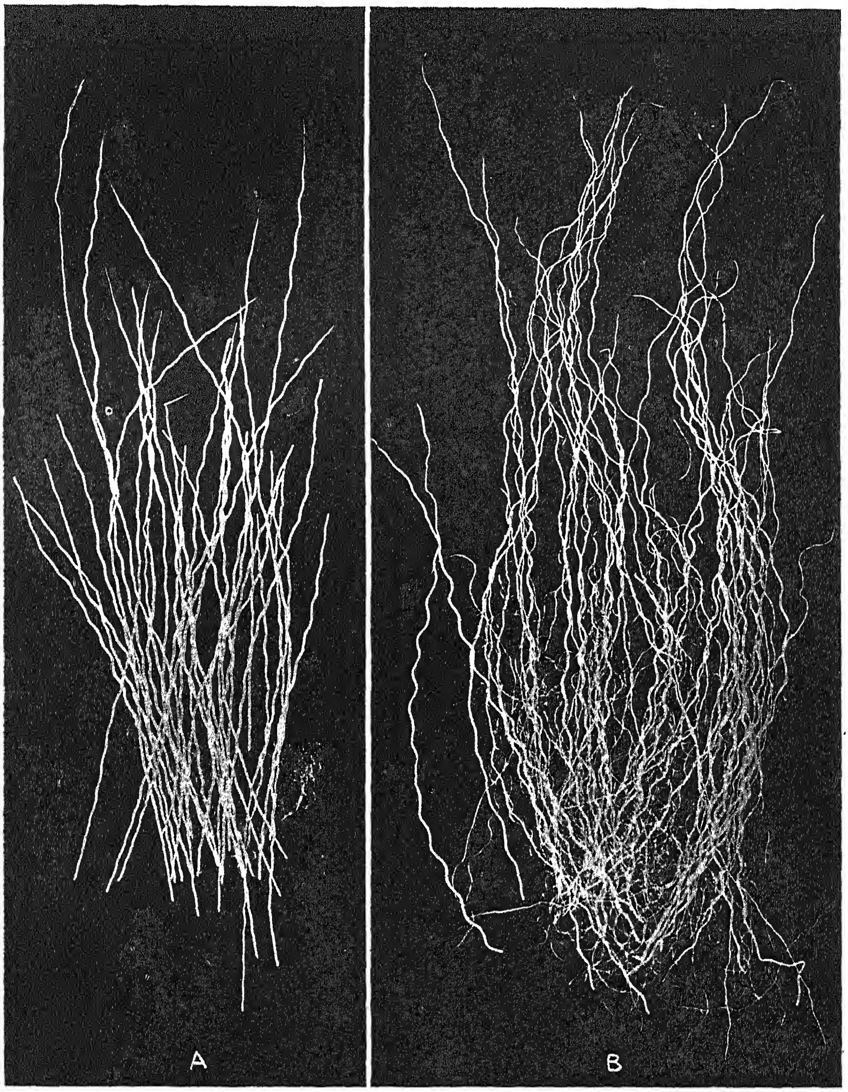
The quantitative estimation of fibres of different classes by weight can be applied to the separation of fibres other than kemp. Although in such cases the distinctions are not so clearly qualitative, it is possible by carefully deciding on standards and preparing a scale of fibres for reference to attain a high degree of accuracy. There is a personal factor in the selection of standards which does not arise in the case of kemp, but still the method is one of considerable usefulness and is being applied to the fleeces of other breeds in this Department.

Kemp in the Welsh Fleece from the Point of View of the Manufacturer

In the opinion of the manufacturer the outstanding defect of Welsh wool is the presence of kemps. The best Welsh fleeces go into the Down grades, being practically as good as Shropshire. Every improvement therefore would simply carry Welsh wool higher in the class it is already in.

It is a matter of great importance to ascertain whether the manufacturer's opinion of what constitutes kemp coincides with the definition that has been reached in the laboratory. Several samples were taken and divided into two portions. From one portion the kemp was removed as in analysis, the other being left untreated. These samples were then submitted for technical examination, the most important point being whether in the opinion of the expert those portions from which the kemp had been removed were really free from kemp in the trade's sense. All the samples were pronounced to be free as far as handling and naked-eye examination went, except in one case where the report stated that one kemp fibre seemed to have been overlooked; this was an anomalous fibre. This close correspondence between the technical definition of what constitutes kemp and that reached on biological grounds is extremely satisfactory.

There are two main points in the grading of Welsh fleece, "kemp" and "quality," and kemp appears to exercise the greatest influence on the value



PART III., PLATE VI.

A—Tuft of coat of *Ovis dalli* (American Bighorn). × 1½.
B—Tuft of coat of very kempy Welsh sheep taken just above hock. × 1½.

of the fleeces. The following table shows the results of the analyses of some Welsh fleeces and the manufacturer's grading chosen quite at random—

Sheep	% Kemp at Shoulder	% Kemp at Rump	Manufacturer's Grading	Manufacturer's Remarks
S 4	0·1	0·5	1	Down character, fine quality, little kemp.
S 59	< 0·1	1·5	1	,, ,, ,, ,,
S 62	< 0·1	3·2	1	,, ,, ,, ,,
S 48	0·5	4·7	2	
S 13	1·2	5·3	2	
S 19	0·6	1·3	3	
S 18	1·5	7·3	3	Long staple.
S 52	2·2	15·7	4	Lowest in quality and most kemp.

It will be seen that on the whole there is good correspondence between the percentages of kemp and the manufacturer's grading. S 18 and S 19, where this does not appear to hold so strictly, were undoubtedly coarse apart from kemp. Red kemp is particularly objectionable; it is dealt with in a separate section.

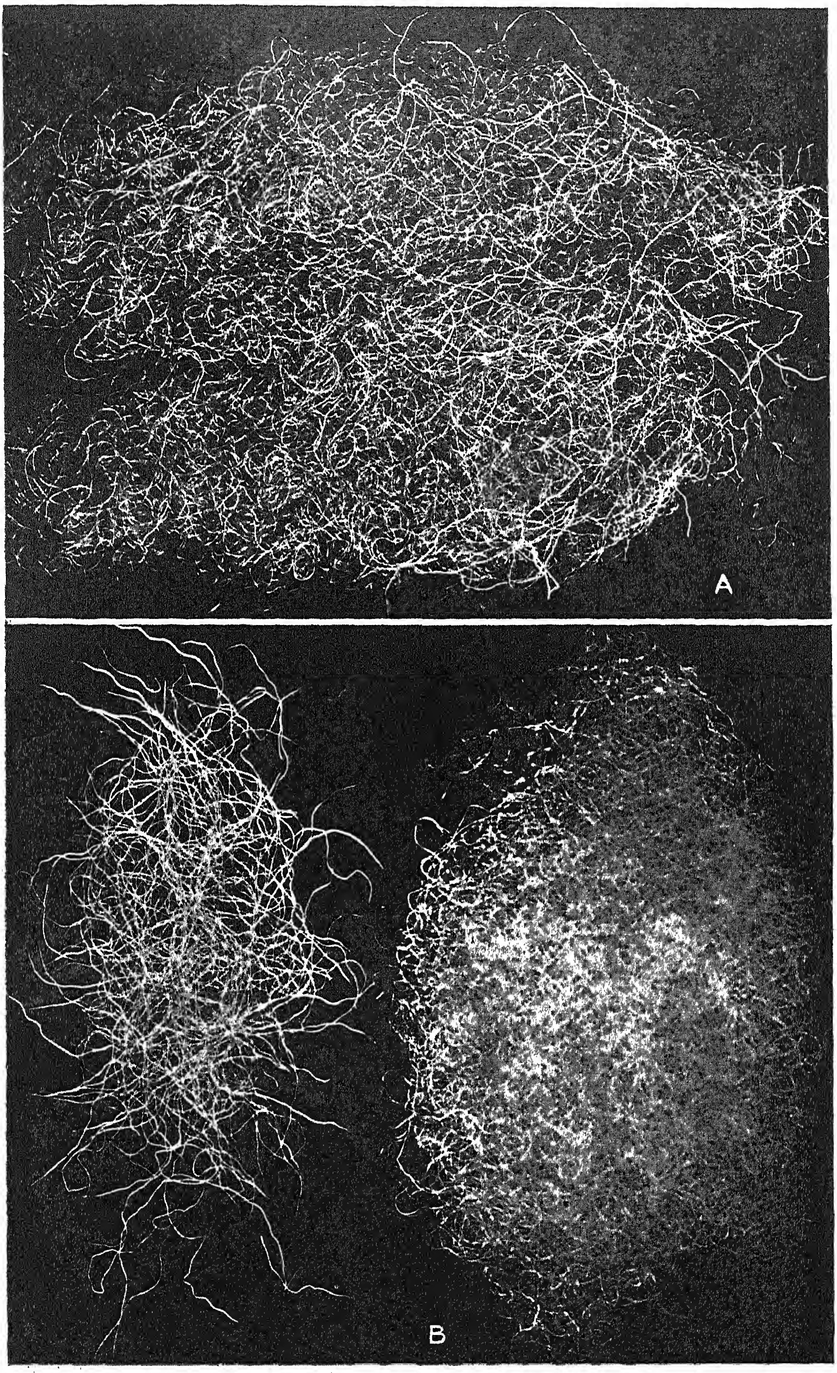
Kemp in the Welsh Fleece from the Point of View of the Sheepbreeder

The consideration of those factors which have a special importance to the sheepbreeder represents a large and important section of the whole scheme of wool improvement. Any detailed discussion of the points which have to be considered would be out of place in the present paper, but as the possibility of any improvement at all depends upon its reasonableness from a practical point of view, and as again the question of kemp is the most important one, a brief summary will be given.

To the breeder of mountain sheep hardiness is a paramount consideration, and the fleece is regarded first of all as an efficient protection or otherwise to the sheep at all stages in its life. Most breeders of Welsh sheep hold that the presence of kemp is associated in some way with hardiness and herein lies the great obstacle in the way of improvement. In order to reduce the breeder's requirements to definite standards, as regards the adult fleece, a scale of points was constructed by Professor White and Mr. R. N. Jones as follows—

(1) *Length*—Optimum length, 10; fleeces that are too short, 9, 8, &c.; those which are too long, 11, 12, &c. The usual fault is that fleeces are too long.
(2) *Density*—This is a point of great importance. A dense weather-resisting coat is highly desirable for mountain conditions. Maximum, 10.
(3) *Absence of Lockiness*—An objectionable feature is the tendency of some fleeces to fall into "locks," thus allowing rain to penetrate. Complete absence, 10.
(4) *Fineness of Fibre*—Greatest fineness, 10.
(5) *Absence of Kemp*—Almost complete absence, 10 (this point was determined arbitrarily by inspection, and the optimum value is, of course, the whole problem).

It was found from the grading of a very large number of sheep that the proportion of kemp was not correlated with any other point. That is, a long fleece may be kempy or not; a short one may be equally kempy or equally free; and so on. Therefore it is possible to conclude that the elimination of kemp would not injure any quality that the breeder values in the adult fleece. On the other hand, it is interesting to note that shortness, density, absence of lockiness, and fineness are pretty closely correlated



PART III., PLATE VII.

A—Sample of Welsh wool (rump). $\times 1\frac{1}{2}$.

B—Same example separated into kemps and non-kemp fibres (16% kemp). $\times 1\frac{1}{2}$.

together and that here the interests of the manufacturer who wants quality and those of the breeder are practically the same.

Another point of importance has to be considered, and in this case the position is not so simple. The coat of the lamb at birth should be thick and weather resisting; it was found that three types of birth coats occurred Welsh sheep—

I.—Thick hairy coat all over.

II.—Fine curling wool on shoulders and fore part of body only.

III.—Fine curling wool all over.

Type III. and the finer varieties of Type II. are definitely unsuitable for mountain conditions. It has also been found that unfortunately there is an association between a good covering at birth and a kempy adult coat, as is shown by the following figures taken from the grading of 180 sheep—

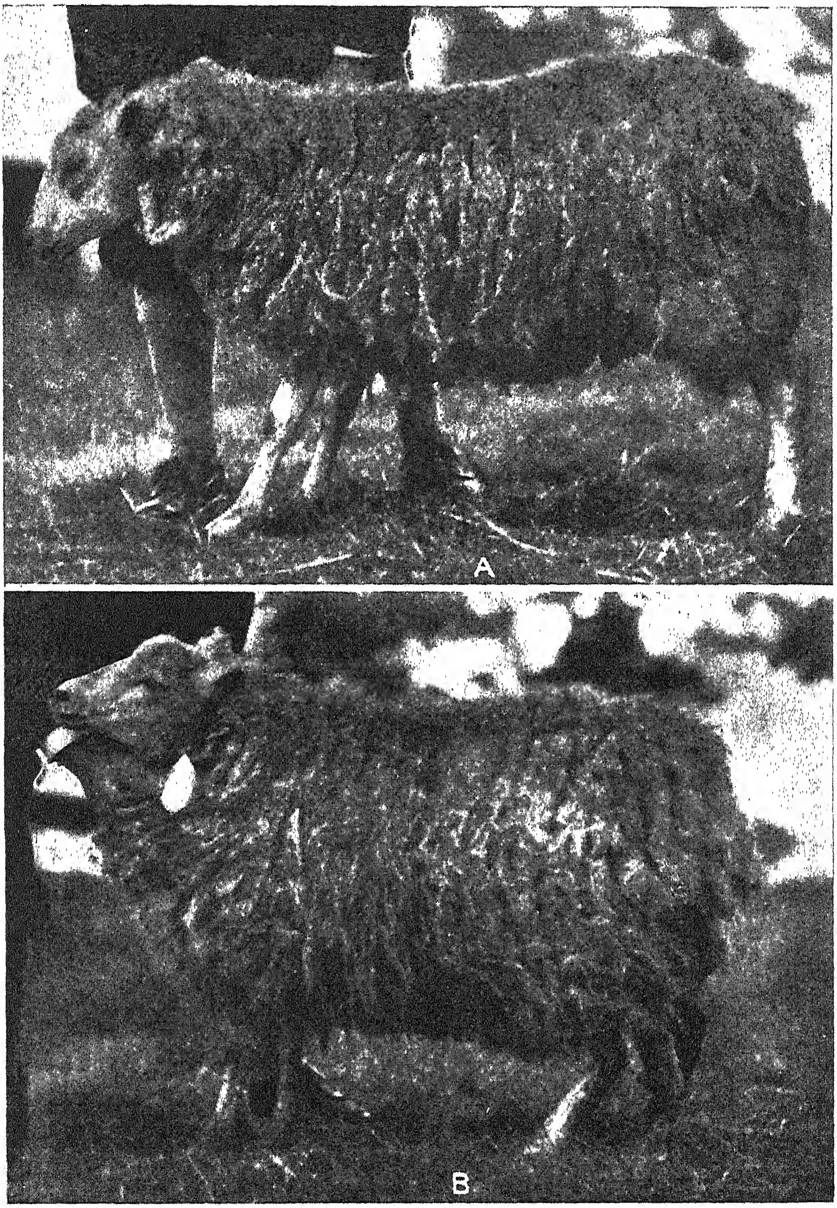
Number of Sheep	Coat at Birth	Breeder's Estimate of points for absence of Kemp in Adult Fleece—Average
52	I.	$6 \cdot 5 \pm 0 \cdot 12$
97	I.	$8 \cdot 1 \pm 0 \cdot 07$
30	III.	$9 \cdot 5 \pm 0 \cdot 09$

Some breeders talk, not of a kemp-free ram leaving stock on the mountain deficient in hardiness, but of such an animal giving rise to progeny with poor birth-coats, and it is probably just this point that is responsible for the belief in a connection between kemp and hardiness. It is also certain that mere selection for fine-coated adults, regardless of anything else, is going to injure hardiness in just this way. However, the problem is not insoluble; the figures above are only an average. In 14 cases out of the 52 sheep of Type I. above, the estimate of kemp was 8–10, so that it is possible to get lambs with a thick coat at birth which are yet relatively free from kemp as adults. The key to the problem lies in the shedding of the lamb's coat. In some cases, such as the 14 mentioned, the birth-coat is shed and does not lead to a thick growth of kemp later. In other cases the birth-coat persists, resulting indirectly in a kempy fleece. Analogous conditions in other breeds make the problem yet more hopeful. For example, in certain merinos the lambs have a thick hairy birth-coat, which is more or less completely shed, leaving a fine adult coat. What the breeder has to aim at, therefore, is the retention of the thick birth-coat and at the same time selection for a lower proportion of kemp; it would be a mistake to secure freedom from kemp by sacrificing the birth-coat. Some breeders will, however, still believe that there is some other and quite obscure connection between kemp and hardiness, and this is a matter that can only be tested by actually observing under mountain conditions the success or otherwise of sheep which come up to specification. The question of the lamb's coat and its relations to kemp will, it is hoped, form the subject of another paper.

Further Considerations

It is hoped that the work outlined above will provide the basis for research in a number of directions. For example, it will be possible to observe the variations in the fleece from year to year, and the importance or otherwise of the effects of environment. It will also be possible to carry out genetical experiments in order to attempt to discover the mode of inheritance of the various characteristics that have been defined.

There are many gaps, but it is hoped that there are sufficient indications that these can be filled up by further work. Kemp determinations are



PART III., PLATE VIII.

A—Welsh sheep with practically ideal coat, kemp not weighable even at rump. Short, dense, and of good quality.

B—Welsh sheep from same flock with long, coarse, open kempy coat.

being carried out on a large number of samples from pedigree sheep that have been graded both by breeder and manufacturer, and in this way it will be possible to link up all these considerations yet more closely.

Red Kemp

Red kemp fibres are undoubtedly kempy in their characteristics but they are not so amenable to laboratory determination as ordinary kemps, because their distribution is not regular; they occur in patches. They are associated with the slightly tan face and legs and also with the tan patches in new-born lambs that are characteristic of Welsh sheep. It will be seen, however, as the work progresses how far, if a reduction of ordinary kemp is effected, the red kemp would tend to be automatically diminished also. It is probable that as much information regarding these fibres will be obtained during the course of work on ordinary kemp as would be secured by any *ad hoc* experiments that could be devised.

Summary

(1) Kemp in Welsh wool is described as regards its naked-eye characteristics, its mode of growth, and histological structure. A hypothesis is advanced as to its origin. This leads up to a definition of kemp.

(2) A method for the quantitative determination of kemp is described.

(3) The importance of kemp to the manufacturer is discussed and the correspondence between the biological definition that has been laid down and the technical opinion of what constitutes kemp is pointed out.

(4) The ways in which kemp affects the sheepbreeder in its possible relations to other qualities of the sheep are briefly discussed, and from this emerges a possible line of wool improvement. The special importance of the birth-coat and its relation to kemp in the adult fleece is also discussed.

(5) A brief reference is made to the occurrence of red kemp.

PART IV.—KEMP FIBRES IN FLEECES OF BRITISH BREEDS OF SHEEP

By Janet S. S. Blyth, Ph.D.

(Animal Breeding Research Department, University of Edinburgh)

The word "kemp" is so frequently used loosely to describe coarse fibres of any kind in the fleece of the sheep or the wool-bearing goats, that it is necessary to begin by making clear the more restricted sense in which it will be used in the present paper. "Kemp" will designate a fibre which is in all but the long-woolled mountain breeds, distinct from all others on account of its coarseness and because it is usually found lying loose in the fleece (especially if the latter is examined towards shearing time); it possesses a complete tip and root from which it may be concluded that it is shed at least once a year. Further, it is distinguishable from all other fibres on account of its relative brittleness and its white and more opaque colouration. The former quality is most noticeable in the longer kemps found in the mountain breeds; in these fibres at intervals along their length are found many "breaks" or transverse bends, caused, no doubt, by the movement of the fleece on the sheep's back and the wear and tear to which it is subjected.

Usually kemp is round or oval in cross-section, and for the major part of its length fairly uniform in diameter, only tapering off for a short distance at its extremities. However, in some of the coarser kemps there is a characteristic rigid waving which is accompanied by slight corresponding undulations in diameter. At the tip it runs out to an extremely fine point; at the proximal end the thinning is usually slightly less and terminates in a small bulbous part. The fibre is composed of the same three concentric rings or layers as those found in typical hair fibre, namely, cuticle, cortex, and medulla. The thin superficial ring of the cuticle is rather characteristic. Medially (i.e. in the thickest portion of the fibre) it exhibits a definite reticular structure, the meshes of which are penta- and hexagonal, the sides being very fine and straight, and angles between them clear-cut. Generally they are fairly uniform in size. On examining the cuticular edges under high magnification, it is seen that the more distal edges project a little and overlap the scales above them.

Travelling towards the extremities of the fibre it is seen that the scales become broader and slightly shallower, the apex angle of the scale becomes more and more obtuse until at last it disappears altogether, when the ectal edge, now more clearly visible as such, is represented by a single smooth continuous line. At first sight they now appear to be identical with large wool scales. However, they have a tendency to possess straighter sides and take the form of long narrow rectangles, whereas the wool type exhibits a faintly ragged edge and curves down to meet the superimposed scale without forming any definite angles. These shallow scales continue along the tapering distal end of the fibre right to the point, but at the proximal end, which when complete terminates in a bulb of loosely packed fusiform cortical cells, the cuticular cells are not present beyond the region where the bulb merges into the shaft of the fibre.

The middle or cortical layer is usually very thin, especially in the coarser forms of kemp fibre, but thickens to a short distance at the tapering root and tip parts, which are invariably formed of cuticle and cortex only. It

F—Root of kemp fibre. ×100.

appears to be homogenous, faintly striated (except for the bulbous root part described above), but may be dissociated and shown to be composed of similar fusiform cells, which are in this case very closely packed together.

The third or centre part of the fibre—the medulla—takes up in all the coarse kemps by far the greatest part of the shaft, and is enclosed by the other two layers in a fine cylindrical shell. Its structure is reticulate; the meshes which are open, except where occasionally torn septæ stretch across them, run both horizontally and vertically, and are apparently the shrunken cells and cell walls of the original medulla, which before keratinisation may be distinguished from the surrounding cortical cells by their round or square shape, as compared with the spindle shape of the latter. As might be expected from its origin, this medullary tracery is thick and uneven, and stands out clearly, so that in fibres with very thin outer layers it is sometimes mistaken for the superficial scale, the fine outlines of which are only visible under high magnification, and even then it may be with difficulty.

Examined by transmitted light the medulla of a complete fibre of this type shows up as a solid black core on the surface of which the outer meshes are roughly outlined; by reflected light it appears as a similar silver rod. This appearance is caused by a gas filling the medullary interstices, the presence of which may be exhibited by pressing a freshly-mounted fibre between the cover-glass and slide, when the gas will be expelled as a stream of bubbles, leaving the medullary structure more clearly exposed. On releasing the pressure some of the bubbles run back into the medulla, but the mounting medium also runs in and prevents their complete return. This is more easily performed on a broken fibre or one in which the medulla has been cut, for in a complete fibre the medulla is entirely encircled and the cuticular and cortical layers must be burst before its gaseous contents can be expelled.

The white opaqueness of the kemp fibres is also due to a great extent to the presence of this column of gas, and disappears when a dry fibre is subjected to pressure or at a broken or crushed part, leaving a translucent portion comparable with the extremities of wool fibres, where no medulla occurs. To this same cause may be attributed the reputed resistance of kemp to dyes. Actually, kemp and wool fibres dye almost equally well, but the refraction caused by the medulla of the former makes the dye appear relatively ineffective.

Modifications of the above type of kemps may be found, which are less opaque and usually short—from 0·5 to 2·0 cm. in length. Under the microscope the chief divergence from the coarse type is the reduction in the amount of medulla, all grades being found, from the reticulate type already described to a fine discontinuous medulla only one cell wide. The cortex is thicker in these fine fibres, so that their diameter does not vary in direct proportion to the size of the medulla. The reticulate scales of the cuticle are often entirely absent, the fibres being clothed throughout by broad shallow scales.

Great variation in length of kemp fibres occurs but does not appear to be definitely correlated with changes in diameter, for while fine kemps are among the shortest, thick kemps from 1 to 15 cm. or longer are found. In a large number of small samples which were examined the length of the kemp fibres was found to be fairly uniform within one sample, but variation was found to occur between different samples of the same breed. Generally coarser kemps were found in the coarser samples, but there are occasional exceptions to this rule. If the breeds are considered in four groups into

which they can conveniently be classified—Mountain Longwool, Lustre Wool, Down Wool, and Mountain Short Wool—it appears that within each group there is present one modification of kemps which is more typical than the rest. Thus in the Down breeds the kemps are short (0·5 to 2·0 cm.) and have a fine or only moderately thick medulla. In the Lustre breeds they are for the most part of the same length, but extremely thick and possess a very wide medulla. In the Mountain Short Wools kemps reach 3 cm. in length and have a fairly wide medulla. The Mountain Longwools contain long kemps (6–15 cm.) with wide medullæ; the only exception is the Lonk breed in which fibres 1–3 cm. long of moderate coarseness occur.

Coloured kemps, as it is to be expected, frequently occur in wool samples from dark-faced breeds. They occur both separately and in conjunction with other pigmented fibres. The extreme tip and root regions of kemps are always free from pigment and apparently it is also absent in the cuticle. In the medulla it is laid down in minute grains and larger granules irregular in size and shape, but without any apparent pattern. In the cortex the former are arranged in short rows closely packed and lying parallel to the length of the fibre. The larger granules appear irregularly through the cortex either separately or in short strings.

Two kinds of kemp fibres have been found in samples from British breeds which must be considered abnormal in their form. The one which in its extreme form occurs only very occasionally is the type in which the medulla thins down suddenly and disappears at unexpected places; in the medial region, for example, where ordinarily the medulla is at its widest, a short piece may be found where it is entirely absent; as is the case in the normal root part the cortex thickens a little in these regions, but the fibre shaft as a whole is greatly reduced in diameter and the thinning is quite obvious to the naked eye. Quite long thin parts of this kind may occur especially at the proximal end, as if the root part had become enormously extended.

The other abnormal type of kemp fibre is that in which it appears to have been mechanically damaged. Such an appearance is only found in kemps with a very wide medulla. At intervals along the length of the fibre breaks appear which take the form of deep kinks in the side of the fibre or of flattened bends similar to the flattening obtained in a flexible rubber tube, when it is bent back upon itself. In the kinks longitudinal splitting of the outer layers of the fibre occur and the medullary reticulum is compressed in the same direction. Sometimes such a picture is accompanied by the collapse of the medulla in the neighbouring parts of the fibre in which case most of the gas disappears from the medulla and the fibre assumes a twisted and flattened appearance in these parts.

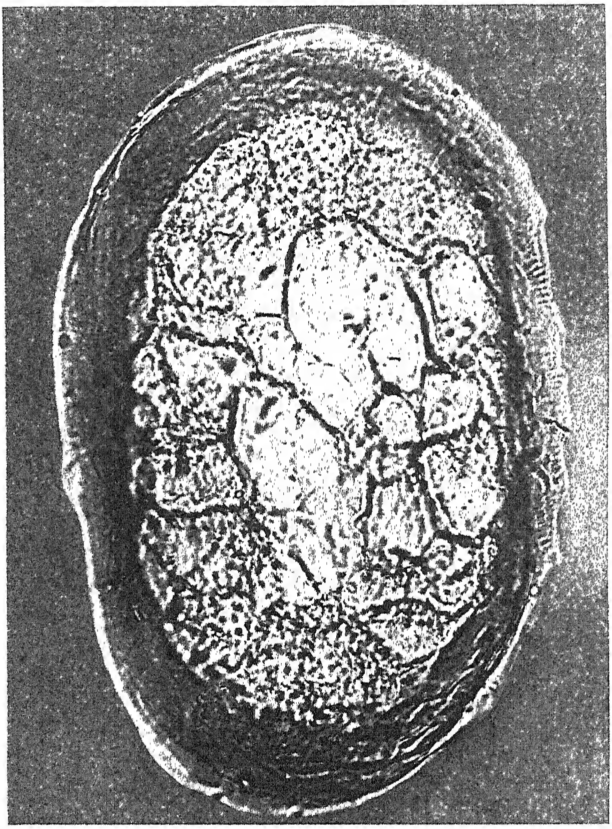
It is generally accepted that kemp is homologous with the hair of the fleece of the primitive breeds of sheep and there would appear to be nothing in the structure and nature of the kemp fibres from British breeds which would lead us to any other conclusion; for while there may be a wide difference between the structure of fine kemps and that of primitive hair, yet coarse kemps are remarkably similar to the latter, and since all gradations between the extreme types of kemps are found, it is reasonable to assume that they are all modifications of one and the same type of fibre.

PART V.—SOME CHARACTERISTICS OF MOHAIR KEMP*

By H. R. Hirst B.Sc., F.I.C. and A. T. King B.Sc., F.I.C.

(The British Research Association for the Woollen and Worsted Industries)

Kemp in mohair possesses the same objectionable features from the manufacturing standpoint as kemp in wool. The characteristics of whiteness



Part V., Plate I.

and lack of strength, elasticity, and apparent dyeing affinity, are due to inclusion of air within a network of cells of honeycomb-like appearance which make up the inner core or medulla of such fibres.

Appearance under the Microscope

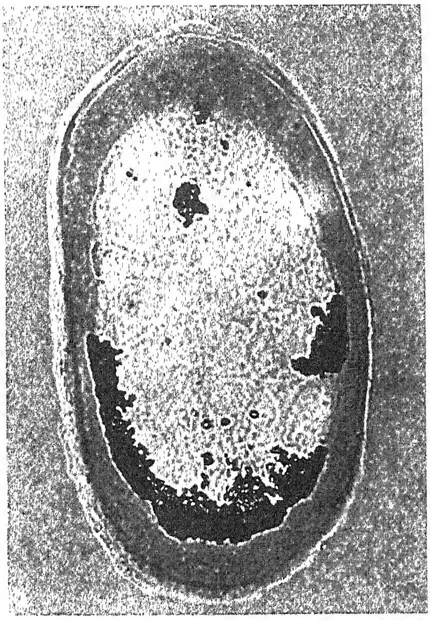
Non-kempy mohair appears, like sheep's wool, to consist only of solid cortical cells sheathed in an outer cuticle, serrated, but less prominently

* These notes are from work carried out in 1921–22 at the instance of the late Mr. Ernest Gates, in connection with the problem of dyeing kempy mohair.

than merino, and more resembling non-medullated Lincoln fibres. It does not contain medulla† (i.e. the inner core running continuously or discontinuously through the fibre, which usually contains air, and is of meshed formation and visibly differs in structure).

Kemp in mohair has not been found as a shed fibre in any of the samples examined. The casual manner of shearing may account in some part for this. The kempy fibres examined all showed cut ends, and it appears that only in the finer grades do the kempy fibres show uncut tips, denoting a new growth.

With the coarser grades the kemp fibres have both tip and root ends cut, and the thickened and heavily medullated portion which usually only



PART V., PLATE II.

runs for about a third of the length of the fibre suggests a marked seasonal variation rather than the annual shedding characteristic of true wool kemps. The regular and continuous medulla traversing the whole length of the true wool kemp, apart from small portions at the extreme ends, has not been found in any of the commercial mohair samples available.

Appearance in Cross-Section

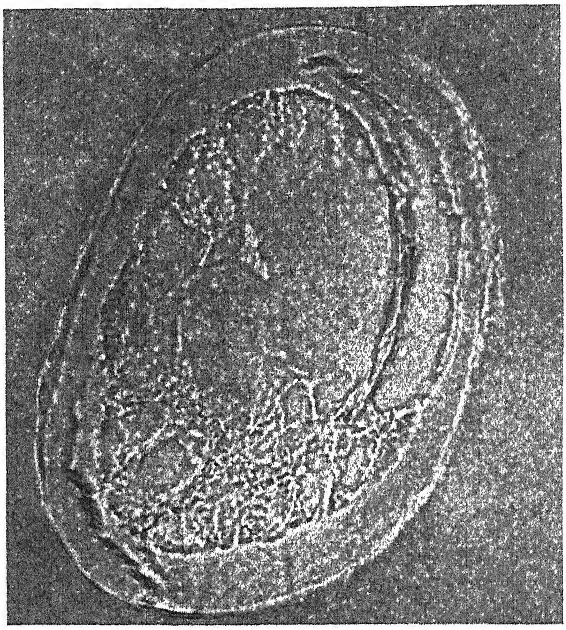
Examination of the fibre lengthwise gives an incomplete idea of the medullary structure, and a clearer insight is obtained from the appearance in cross-section. From the photographs reproduced in Plates I.–VI., it will be observed that the network of hollow cells is continuous across the section.

† Mammalian hairs in general are made of three layers—Cuticle, cortex, and medulla. The fine mohair fibres of the Angora goat are, however, practically free from medulla. A sample of these fine fibres separated from kempy mohair "beard," the lowest grade, showed an average diameter of $2{\cdot}5 \times 10^{-3}$ cm., which corresponds with about 56's quality wool. They are, if anything, more translucent, and softer in handle, than wool of that quality. They are somewhat shorter than the coarse kempy fibres.

The attachment of the network walls to the cortex or solid portion of the fibre is also clearly shown, particularly in Plates I. and VI. Plate II. illustrates the partial replacement of the air from the cells by the mounting medium, the air-containing cells showing up black. These sections were cut with the microtome set for a thickness of 0·002 mm.

Plate III. is of interest as showing a fracture in the cortical layer, and a partial tearing away of the medulla substance.

Especial reference is made to Plate IV., which is a photograph of a wedge-shaped section, obtained after much difficulty by first making an oblique cut and then slightly altering the angle. The section is pared down to practically a single thickness of the medulla structure, and it shows the



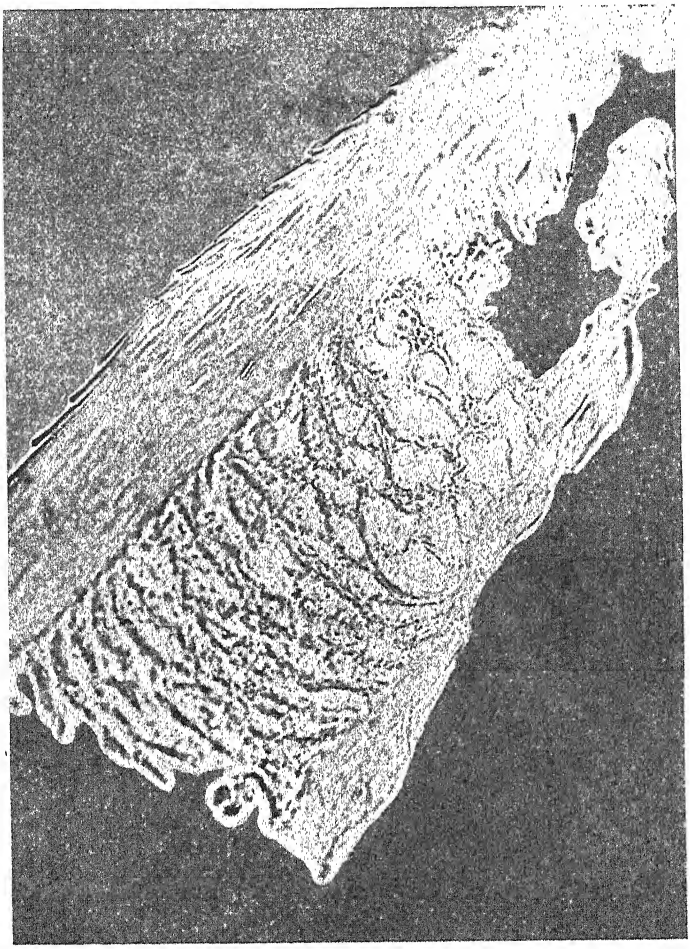
Part V., Plate III.

open nature of this network almost unobscured by underlying layers. Plates V. and VI. show portions of this section under higher magnification.

It will be noticed that the sections as a whole are irregularly elliptical in shape. All wool fibres in fact are stated to be elliptical in cross-section. It may be noted, however, that cross-sections of a perfectly cylindrical fibre would appear elliptical if not cut at right angles to its axis. Also the bean-shaped section in Plate II. might easily be produced from a round fibre containing a yielding interior, with the knife cutting through from the side now showing concave. Markedly flattened fibres are easily recognised by their ribbon-like and twisted appearance when viewed longitudinally, but this is certainly not the case in kempy mohair, which appears very straight and rod-like, even when the solid layer is quite thin.

Mohair fibres measured in the Polikeit instrument, which permits of the fibre being rotated without twisting, so that its diameters at right angles can be measured, do not in fact show a marked difference in these diameters, provided the solid layer is not unduly thin. It is worthy of

note that where differences in these two diameters occur, measurements along the fibre show a definite undulation, the major diameter alternating from one direction to that at right angles to it. This suggests a cylindrical rubber rod distorted by applying a torque or twist to one end. The effect is especially observable with merino fibres, but is practically absent with



Part V., Plate IV.

coarse Lincoln fibres. In making these measurements, to avoid confusion in keeping to the same two directions at right angles, observations were taken with successive rotations of 90°, so that when the fibre was moved lengthwise, and the four measurements repeated, they were always in the same directions for every point. The first and third, and second and fourth were then averaged, to give the diameters in the same two right-angled directions along the fibre length. The example given is of an English 56's fibre, measurements being taken at successive intervals of 0·01 cms. along the fibre. The actual diameters are obtained in millimetres by multiplying by 0·0024.

The smoothed curves, following the trend of the fluctuating values, are shown in the accompanying graph.

Method of Cutting Cross-Sections

The usual method of simply embedding in paraffin wax, or gum arabic and gelatine, is unsatisfactory in the case of wool, as the fibre does not bear sufficiently firmly against the knife edge.

Reisner's method of embedding between two layers of guttapercha, first melting the guttapercha and then laying the fibres parällel and covering with another layer of guttapercha, is rapid, but not suited to the cutting of thin sections in the microtome. For examination by reflected light, however, where comparatively thick sections cut with an ordinary razor can be used, the method is very convenient.

Willows (*J. Text. Inst.*, 1921, **12**, 99) found that cotton cross-sections could be obtained by treating the fibres with a solution of cellulose acetate in acetone before embedding. We have not been able to apply this method satisfactorily to wool fibres.

Completely successful results are, however, obtainable by the method given by Denham (*Nature*, 1921, p. 299), a modification of Brechner's method, to which reference has already been made (Private Report, No. 11, p. 34). It consists in soaking the fibres, first in alcohol-ether, and then in a solution of celluloid in alcohol-ether, after which they are transferred to a chloroform solution of paraffin wax, allowed to soak for two hours, and then quickly embedded in paraffin wax. It is important that the outer layer of wax be thick and firm. The sections, cut to the desired thickness in the microtome, are examined on a slip, and when a suitable specimen is obtained, another slip, coated with a thin film of the albumen-glycerine solution recommended by Denham, is placed carefully over it and gently pressed until the section adheres. After gentle warming to allow the wax to sink flat on the slip, the wax and celluloid are removed by soaking in benzene and acetone respectively, and the section then mounted in an appropriate medium.

We find, however, that with thin sections the albumen layer, which gives a distracting background, can be dispensed with. The wax section is melted flat on a clean slide, carefully washed with successive drops of benzene to remove the wax and mounted with Canada balsam in amyl or butyl acetate. This dissolves the celluloid support or makes it transparent. If required for examination in air, the celluloid support is removed by careful application of butyl acetate, which can generally be accomplished without washing the section off the slide.

Even with very kempy hairs, which are difficult to cut on account of their brittle medulla, and consequent tendency to tear, this method has given very satisfactory results.

PART V., PLATE V.

The Problem of Dyeing Mohair Kemps

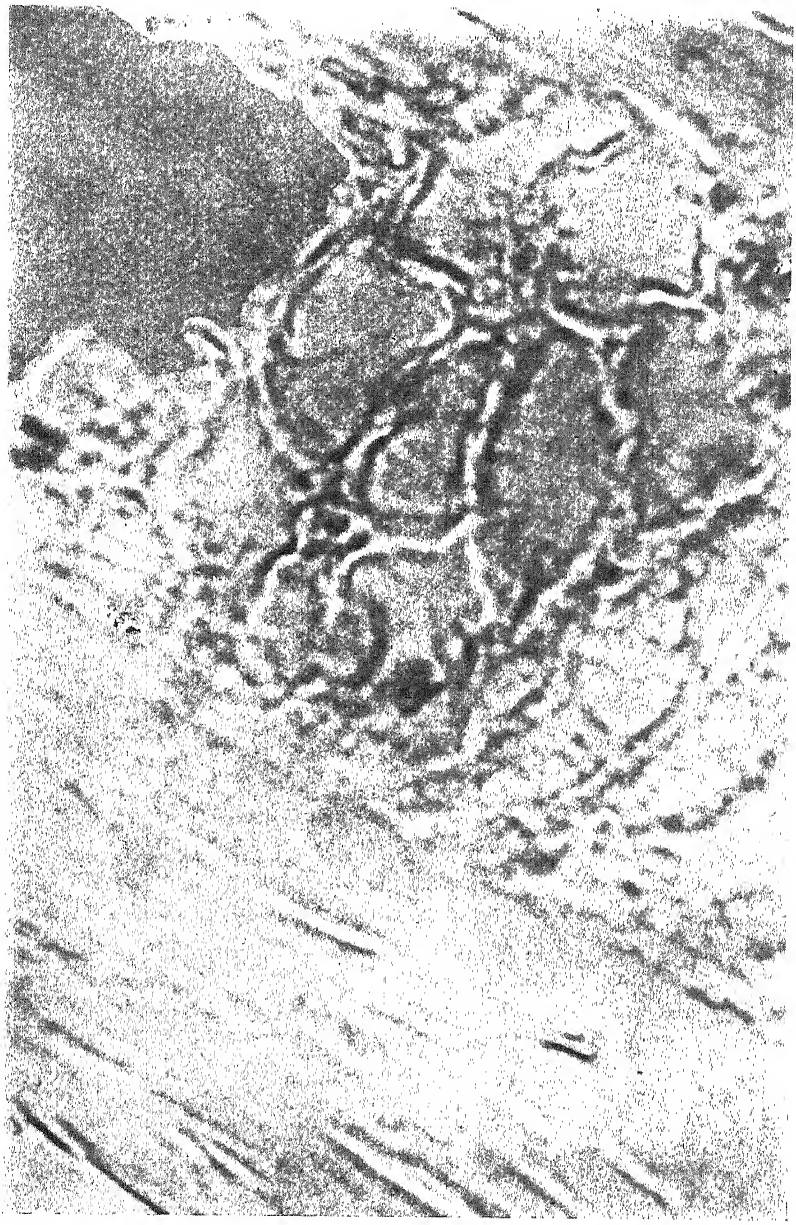
The difference in appearance between a solid fibre and one containing medulla may be compared with that between a solid glass rod and a glass tube filled with small glass fragments. The difference is apparent both with plain and coloured glass. Even if the tube be filled with glass fragments of deeper colour, it may still appear lighter in shade than the rod, owing to the great degree of reflection taking place from the broken interior.

Cross-sections of dyed fibres show the actual medulla substance to be dyed equally with the solid portion. It is thus evident that the trouble is due entirely to the enclosed air, the effect of which shows up with any colour except black or very dark shades.

Thus the solution to the problem requires either the filling up of the air spaces with material of similar translucency to that of the fibre substance, or the breaking down of the interior network. In the latter case the analogy of the glass tube and rod may again be used. A hollow tube more nearly matches the appearance of a rod of glass of the same colour than one packed with glass fragments.

Attempts to solve the problem on the foregoing lines did not yield any satisfactory result. Volatile liquids like alcohol and benzene penetrate fairly readily, but all attempts to introduce materials which would permanently fill the air spaces failed. For example, fibres were placed in gelatine and various other solutions under a high vacuum, with a view to getting the liquid to enter the hollow cells, but the replacement was at the most only partial and chiefly confined to fractured places in the cortical layer. Efforts were made to replace the air by diffusion with soluble gases, i.e. sulphur dioxide and ammonia, but no marked penetration was observed when the treated fibres were placed in an appropriate absorbing medium. Attempts to break down the cellular interior were also unsuccessful. Mercerising with strong caustic soda failed to remove it. Barium sulphocyanide and concentrated bisulphite were without effect. Efforts to minimise the difference in appearance, on the one hand, by giving the mohair as a whole a greater gloss, e.g. by chlorination, and on the other by producing a general matte effect, by treating first with dilute sulphuric acid and converting this into barium sulphate by means of barium chloride solution, were also abortive.

If there is a solution to the problem it appears more likely to be in the direction of mechanical rather than chemical treatment, as it is difficult to conceive a chemical treatment sufficiently drastic to destroy the medulla structure, without impairing the material as a whole.



PART V., PLATE VI.

28—VI.—TENSILE TESTS FOR COTTON YARNS
i.—A SURVEY OF CURRENT TESTS

By Edward Midgley, B.Sc., and
Frederick Thomas Peirce, B.Sc., F.Inst.P.
(British Cotton Industry Research Association)

INTRODUCTION AND SUMMARY

The numerical result of a test depends on many things quite distinct from the practical quality of the yarn, that is its ability to withstand the strains imposed in industrial processes and wear. These foreign effects must be understood and controlled if a sound practical judgment is to be based on the test. In this series of papers the tests available are analysed from this standpoint, the first giving a general survey and an analysis of the lea test, the method most generally used. As the record of experience in this laboratory, this may be of practical utility to other testing departments, though no claim is made that the statements are all original.

The necessity for testing, and more accurate testing, is emphasised under modern conditions by the greater intensity of competition, new developments such as unions with artificial silks and the increasing supply of unfamiliar varieties of cotton. Testing hastens the gathering of experience on the problems thus raised, and puts it on a basis independent of the personal equation. Yarn testing provides the most direct control, for yarn quality limits that attainable in the fabric and is the criterion of the value of the raw cotton.

Tensile strength, for which alone yarn is commonly tested, does not entirely define the textile value, which is also affected by extensibility, elasticity under moderate tension, flexibility, diameter, regularity, external appearance, snarling twist, and resistance to wear. In the ideal test, the routine will be based on scientific method, while the character measured is chosen with a single eye to practical needs.

The objects of testing are to gain information on (A) the textile quality of the yarn, (B) the technique of spinning, or (C) the quality of the raw cotton. Success in the first object is necessary to that in the others, and the test must be made as close an indication as possible of the way in which the yarn will make up into a fabric. Whatever the object, the first condition for a sound judgment is that one variable factor only must enter; for example, to compare two yarns, the conditions of testing must be identical; to compare the efficiency of two cards, draw frames or humidities in spinning, the mixings, other spinning processes and the testing must be kept identical; to compare two cottons, they must be put through the same machines and tested under the same conditions.

The numerical test result, however, on which opinion must be based, depends not only on the textile quality of the yarn, the object of the test, but also on the following factors, taking them as they arise in the test routine—

(1) Sampling.
(2) Nature of test.
(3) Efficiency of instrument.
(4) Atmospheric conditions.
(5) Length of specimen.
(6) Rate of break.
(7) Expression of results.

Faulty control on any of these points may make the test deceptive.

An analysis of each of these factors is given in this and the following papers, though for convenience they are not discussed exactly in the above order.

Sampling and Expression of Results

That the strength of the broken test pieces should yield information on the strength of the batch as a whole, the sampling must be true and the results suitably expressed. Methods of sampling necessarily vary with the object of the test. In general, known sources of variation should be avoided in any single batch, and sufficient specimens from numerous positions tested in order that the result may represent the whole, not merely a chance portion. The arithmetical mean is then taken as the measure of the strength of the batch. To what extent this is true can only be judged from the differences between individual results; the mean alone is not sufficient.

A simple calculation doubles the value of a result, namely, to find the *mean deviation* (M.D.) which is the average difference between the mean and the individual values. Expressed as a percentage this is a sound measure of the irregularity, a low value of which is itself desirable as a regular yarn is more economical of material, easier to handle, and better in the fabric.

Yarn is never designed to bear a strain liable to injure the places of average strength. There is a large factor of safety, and the strength, as a practical quality, depends rather on the number of places where the breaking load falls below a dangerous minimum. This can be found directly from the mean deviation, so also can the probable amount by which the mean obtained may differ from the mean value for the whole batch.

In trying to isolate some effect, such as that of humidity or mercerising or a spinning process, the great irregularity of cotton yarns makes it difficult to measure the real difference caused by the change, for quite large differences may be due to sampling alone. The latter may be diminished by increasing the number of tests, but this adds to the work, and its value is limited by the nature of spinning.

Local irregularities are produced by the variability of cotton hairs and by the way they draft in the final spinning processes, and these are troublesome enough. But, like a ground swell under waves and ripples, longer variations are introduced by changes in the mixing, variations in the lap or in humidity, and by differences between spindles. So irregularity is not diminished by taking larger specimens and samples to the extent expected from calculations on the inch-to-inch irregularity, and the larger a batch of yarn the more irregular it is.

For many purposes this irregularity may be overcome by a simple device, namely, to wind a number of turns on a wrap-reel, fix sticking plaster at two opposite points, and cut into two lots. Each of these *cut-skein samples* contains the alternate threads of the same length of yarn, and the means given by the two are very closely identical when similarly treated and tested. Control tests which are described below show a difference on 40 threads of less than ½ per cent., less than 1/10th the difference on the same number of tests even on consecutive lengths from the same cop. This device has been used when measuring the effects of humidity, rate of loading, tendering by light, acid treatment, rubbing, &c., many of which could never otherwise have been detected, being lost in spinning irregularities when comparison is made between two independent samples. The amount

of testing may be diminished with little loss in precision by winding on a large reel and making a number, say eight, similar samples at a time.

Atmospheric Conditions

To anticipate a more complete account, the breaking load and extension of a 36's Sakel yarn were found to increase by about 5 per cent. of the value at 70% R.H. (relative humidity) for an increase of 10% R.H. Such an example shows that it would be unfair to compare two yarns on results obtained at different humidities, and that all tests should be carried out on yarns conditioned and tested under standard conditions. Taking into consideration normal conditions to which cotton materials are exposed in mills, weaving sheds and warehouses, in use on and off the human body, and the general practice of testing houses, the standard 70% R.H. at 70° F. has been adopted for this work and future testing by the methods described.

The results given in the present papers were obtained in a testing room controlled by a plant which circulates air saturated at a known temperature (the dew point) and maintains the room at a higher temperature. A room may also be controlled by a plant which drives a current of air through either a drying or moistening chamber, according to the properties of a hygroscopic control, the weight of a fabric[5] or the length of animal hairs.[4]

In the absence of full control, the specimens may be conditioned beforehand in a *humidified box*[1], the room humidity being kept as near 70% as possible by heating and ventilation. In the present experiments the specimens were conditioned overnight in such a box, built with double walls of asbestos sheeting and containing control solution, thermo-regulator, and ventilated hygrometer. As a minimum, temperature and humidity records may be kept, but the corrections are uncertain and variable.

Efficiency of Instrument

The breaking load is not directly observed in testing, but only a reading on an instrument scale. The exactitude with which the actual force on the yarn is given depends on the design and calibration of the instrument. The scales are calibrated by the steady reading due to a hanging weight, and even when in perfect order an instrument may give readings different from the actual force because calibration is done with the parts still, whereas in testing they are moving. Under the latter conditions any frictional resistance on parts moved by the recording grip is subtracted from the true tension. A less obvious error is introduced by the momentum of moving parts, if the velocity alters during the tests, for it takes force to change rate of motion. The errors and limitations of machines commonly used, when properly calibrated and in perfect order, are discussed analytically in Paper IV. of this series.

The scale of a *deadweight machine* is very sensitive, the limit of reading being only a fraction of 1% of the breaking load, and small compared with the variations along a yarn, tested on an instrument of suitable range. The friction is negligible if the lever be mounted on ball bearings and the pawls press lightly on the ratchet of the scale. Momentum errors are negligible at ordinary speeds. An eccentric roller (*vide* Paper IV.), which gives a very even scale and rate of loading, greatly improves the single-thread tester used in the present work.

A possible error in the single-thread test may be caused by loss of twist in handling, but can be avoided with due care. Readings of breaking load

can then be accepted as the maximum tension in the yarn, when the machine is properly used. The lea tester is also sufficiently accurate from this point of view.

Extension readings in the lea test, as generally carried out, have little significance and are usually ignored. On the single-thread tester they have great value, and a device is usually incorporated for measuring extension, the simplest being a rod which moves with the lower grip till rupture. Its efficiency depends on a nice adjustment of the weighting of the lever on the lower grip, and the friction which holds the rod after rupture of the specimen. The initial tension affects the extension reading. It may be adjusted by hanging a weight on the specimen before fastening in the lower grip or by a slight displacement of the recording lever, but the advantage is doubtful, as this increases the danger of loss of twist and slip in the grips and the tension may be altered in fastening. The apparent extensibility may also be altered by previous tension, as in winding, which takes out a useless, inelastic extension without causing any real change in extensibility as a practical quality. The reading scale is not sensitive, about 1 in. movement in all, even on long spans. In fine, single-thread extension measurements need close watching, and some degree of uncertainty attaches to such results.

The *Moscrop machine* performs the single-thread test automatically at a much greater rate than the standard deadweight tester, giving a permanent record, and there is little danger from loss of twist. It is shown in Paper IV., however, that these advantages are accompanied by serious momentum errors unless the speed is reduced below the usual rate of 8 cycles per minute, especially with weak yarns. The operation is seriously affected by careless treatment of springs and by dirt on bearings, there being much more to go wrong than in deadweight machines, but the springs are accurate at all speeds and the friction is negligible when the machine is in good working order.

The scale is as sensitive as the regularity of yarns demands, for it was found by trial that neither the mean nor the mean deviation was appreciably changed by reading to one-tenth of an interval. The pendulum type of scale is, indeed, unnecessarily sensitive, and the large intervals of the Moscrop record are a distinct convenience in calculation.

Nature of Test

Let it be granted that a good representative sample has been taken, tested under controlled conditions on a reliable instrument, and that a mean figure of known statistical significance has been obtained which truly describes the batch under test. What information does this figure give as to the real strength of the yarn, that is, whether it will stand processing or will break in winding, doubling, dressing, weaving, or knitting? This depends on the nature of the test itself, and its relation to the strains which the yarn has to stand in practice.

Actually, yarns are not often employed for lifting weights, like a metal chain, and the effective strength of a yarn depends more on the amount of quick extension it can undergo without injury than on breaking load. The usual test for metals is, quite soundly, to measure the force which injures or breaks the specimen under a slowly increasing tension, and this has been adopted as the standard test for textiles. Many other tests—wear, oscillating, stress-strain, ballistic—are conceivable and practicable,

which may give better measures of strength. But though the information it gives is not so directly practical as in the case of metals, the breaking load under steadily increasing tension is a simple criterion, and necessary to the full interpretation of more thorough tests, description of which will be deferred to subsequent papers.

Determined as it is by the slipping and rupture of fibres at the weakest part of the length, the breaking load is not a single-valued quantity characteristic of the yarn alone, but depends on the rate of break and the length of specimen, which may vary in different tests and processes of manufacture.

The effect of the rate of break is described in Paper III. of this series, where it is shown that the yarn offers more resistance to a rapid strain but breaks at the same extension.

Length of Specimen

The longer the specimen of a given yarn the weaker will its weakest spot be on the average, hence the lower the mean breaking load, irregular yarns showing the greatest change. The effect is analysed mathematically in Paper V., where necessary relations are found between the mean strength and irregularity of specimens of different length. Experimentally it was found that the breaking load dropped by about 6% on increasing the length of specimen from 10 in. to 30 in., whilst the extensibility decreased in direct proportion and the mean deviation of breaking load by about 10%. Within the limits of statistical uncertainty, and allowing for known deviations from the normal random distribution of strength, the observed effect of the length of specimen agreed with that deduced theoretically.

From the standpoint of making test results agree with practical behaviour, it is advisable to test lengths of the same order as the free length under tension in processes such as winding, doubling, dressing, weaving, &c. A long specimen, the usual 24 or 27 inches, is desirable on this account as well as because of the greater regularity and more accurate measure of extension.

The Lea Test

In this, the most universal yarn test, a lea of 120 yards is tested in the form of a skein by a gradually increasing tension, which distributes itself more or less evenly among the 160 threads. The thread in which the tension first exceeds the breaking load snaps, others follow, the remainder begin to slip, and the machine records the maximum force transmitted during this process.

Yarn is not used in the form of such skeins, the strength of which is only of interest as a guide to the average strength of individual threads. The criterion by which to judge the results of the test is then the ratio between the lea strength and that of 160 single threads, which will be called the "lea ratio" and expressed as a percentage. As it is not nearly 100%, the lea test is certainly not a direct measure of thread strength. It is usually about 75%, but may vary even from 50% to 90%. The test is therefore not a reliable index to thread strength, for obviously it may make a yarn appear weaker than another when it is really half as strong again.

To inquire what the result depends on and what it really measures, it will be found convenient to divide the total result into two parts, (A) the load registered when the first thread breaks, and (B) the increase that occurs during the process of breaking and slipping. They depend chiefly on the

yarn properties, (1) thread strength and its variability, (2) extensibility and its variability, (3) roughness; and on the testing conditions, (4) placing on the hooks, (5) rate of break.

Even single-thread strength shows a variation with the *rate of break*, but this is a real property of the yarn and inappreciable over the range of speeds of lea testing. The effect on apparent lea strength is more serious as high speed gives the threads near a broken one less chance of slipping, thus increasing the indeterminate part (B) of the result. Standardising the rate of fall of the lower jaw does not ensure the same rate of break on different machines, and even on the one instrument weak specimens are broken more quickly than strong ones. Gégauff[2] has noted that strong leas give a lower lea-ratio than weak ones. It is not practicable to arrange for a constant time of break, and it is best to minimise the indefinite portion (B) of the load by reducing speed. The practice of exaggerating the result by speeding up the machine exaggerates its errors only.

A great difference in the evenness of tension and gripping of the threads may be made by the manner of *placing the lea on the hooks*. Comparison tests showed that a difference of about 15% was made by releasing one end of the lea after winding, this causing the threads to overlap one another in the test. Even putting the lea on with a twist or half-hitch made less difference. A considerable part of the result is still of the type (B) when the lea is in the form of a ribbon, without overlapping of threads. This is shown by the fact that the strength per thread is about 15% less for quarter leas than for full leas, though the first break must occur at a lower tension in the latter.

No definite relation can be found between yarn properties and lea ratios in the ordinary test in which the result varies indeterminately between that which would be given if the threads could not slip at all and if the maximum reading occurred when the first thread breaks. The latter figure can be simply calculated from the analysis given in Paper V., from the mean single-thread strength and the mean deviation of the extensibility. It can be realised by testing quarter leas in a regular band at a reduced speed, the resulting figure being a useful measure of single thread quality, especially as the regularity of extension is a useful property itself. In the ordinary test, results on five types of yarn give an average lea ratio of 81%, calculated ratio to the first break of 71%, the difference being due to a very irregular addition of load after the first break. The iregularity of lea strength was found to be of the same order as that calculated, which is much greater than that of the mean of 160 threads. In fact, 8 single-thread tests give a mean as precise as the result of a lea test. These conclusions are supported by an analysis of extensive data on single-thread and lea strength given in a recent paper by Hall.[3]

DESCRIPTION OF EXPERIMENTS

Control Test on Single-Thread Strength of a Pair of Cut-Skein Samples

The mean breaking load in grams on 40 threads of 36's Sakel unsized yarn was—

(*a*) $359{\cdot}7 \pm 3{\cdot}3$ Difference $1{\cdot}6 = 0{\cdot}45\%$ of the mean.

(*b*) $358{\cdot}1 \pm 4{\cdot}7$ P.V. of difference $= \sqrt{3{\cdot}3^2 + 4{\cdot}7^2} = 5{\cdot}74$.

If one set had been treated, e.g., mercerised, the difference shown would have been almost entirely due to that treatment, even though, from the

variability of each lot taken by itself, only a difference of $3 \times 5{\cdot}74 = 16{\cdot}2$ would be regarded as significant. Disregarding the division into two complementary sets, the mean breaking loads were—

First 40 lengths 370·5.

Second 40 lengths 347·3. Difference 23·2=6·47%.

Had one set of tests been made on 30 yards of yarn and another on the next 30 yards, the difference due to sampling alone would have been 23·2, fourteen times that between the sets of alternate threads, and any small effect due to treatment would have been entirely swamped.

Control Test on Sized Yarn (otherwise as above).

(*a*) $399{\cdot}0 \pm 4{\cdot}7$ Difference 1·2=0·30% of the mean.

(*b*) $397{\cdot}8 \pm 5{\cdot}7$ P.V. of difference 7·4.

Length of Specimen

If the breaking loads of short specimens be distributed about a mean value according to the normal law of deviation, then the decrease in the mean for a greater length is proportional to the mean deviation for the short length and to a factor depending only on the ratio of the lengths. If r be the ratio, v the factor,

$$v = 5{\cdot}3\ (1 - r^{-\frac{1}{5}})$$

very approximately. The variability also decreases, so that the ratio of the mean deviation of the long to that of the short specimens (u) is $r^{-\frac{1}{5}}$.

The variation with length was measured on several yarns by testing alternate specimens of 10 and 30 inches, also by measurements on consecutive lengths of 10 and 30 inches, with the results shown in Table I. (Variability is measured with a little more accuracy by the Standard Deviation, the square root of the mean square deviation. This was used in analysing these results, the M.D. given being 0·798 times the S.D., as for a normal distribution).

Table I.

Observed Effects of Length on Single-Thread Test.

Sample	No.	Length	Breaking Load in gms.	M.D.	Extension %	Difference of Breaking Loads, grams
36's Sakel	277	10″	$367{\cdot}8 \pm 1{\cdot}5$	28·8	6·84	
(*alternate*) ...	277	30″	$359{\cdot}6 \pm 1{\cdot}3$	26·5	6·96	$8{\cdot}2 \pm 2{\cdot}0$
36's Sakel	100	10″	$392{\cdot}9 \pm 2{\cdot}6$	31·2	7·82	
(*consecutive*) ...	100	30″	$370{\cdot}3 \pm 2{\cdot}0$	23·7	6·91	$22{\cdot}6 \pm 3{\cdot}3$
32's American ...	200	10″	$207{\cdot}4 \pm 1{\cdot}2$	17·6	6·01	
Ring Yarn ...	200	30″	$196{\cdot}4 \pm 1{\cdot}1$	16·0	5·93	$11{\cdot}0 \pm 1{\cdot}6$
20's Waste	200	10″	$264{\cdot}0 \pm 2{\cdot}9$	49·1	8·50	
(*alternate*) ...	200	30″	$235{\cdot}4 \pm 2{\cdot}8$	46·6	5·97	$28{\cdot}6 \pm 4{\cdot}2$
20's Waste	100	10″	$291{\cdot}0 \pm 3{\cdot}1$	36·5	7·83	
(*consecutive*) ...	100	30″	$236{\cdot}9 \pm 3{\cdot}6$	42·6	6·68	$54{\cdot}1 \pm 4{\cdot}8$
32's American ...	600	9″	$234{\cdot}1 \pm 0{\cdot}7$	19 4	7·24	
Ring Yarn ...	600	27″	$220{\cdot}0 \pm 0{\cdot}6$	17·5	6·81	$14{\cdot}1 \pm 1{\cdot}0$

When the length is trebled, the theoretical difference is 1·05 times the mean deviation of the short length; the M.D. of the longer specimens is 0·74 times that of the shorter. As these values are based on probability

considerations, the actual ratios over 100 or so specimens must vary widely. The observations show an invariable decrease with length, the changes being greater in the more irregular yarns and of the order to be expected. The M.D. also decreases, but less than the theoretical amount.

The most crucial test is that shown at the bottom of Table I. The samples were two complementary sets of 30 lots of 20 threads. The M.D. of breaking load was found on each lot separately, the mean value for 9″ specimens being $19{\cdot}42 \pm 0{\cdot}58$, for 27″ specimens $17{\cdot}53 \pm 0{\cdot}52$. The ratio of these is $0{\cdot}903 \pm 0{\cdot}038$, which is greater than the theoretical 0·74 by 4·3 times its probable error. Of the 30 differences between the means of complementary twenties, 28 showed the 9″ threads stronger, the mean being $14{\cdot}1 \pm 1{\cdot}0$. The theoretical difference is $1{\cdot}05 \times 19{\cdot}42 = 20{\cdot}4 \pm 0{\cdot}6$. The difference between these two values is 5·4 times its probable error. The ratio of the percentage extensions is 0·94, the same as the ratio of breaking loads.

The changes are significantly less than those deduced from a normal random distribution, as that does not apply strictly to a yarn. The average difference between consecutive pieces is less than between pieces taken at random and it is the former that determines the effect of length. When multiplied by 0·707 ($1/\sqrt{2}$) it should give a figure the same as the mean deviation, if the distribution be normal. Calculated from the consecutive threads, this figure was for 36's Sakel 28·1 against a M.D. of 31·2, for 20's waste 30·6 against 36·5.

For any given thread, the curve of load against extension is very nearly a straight line. The total extension is merely the sum of the extensions of all the portions, consequently the extension as a percentage of the length should be proportional to the breaking load, when the length of specimen only is altered. Measurements of extension are less accurate than those of breaking load, and therefore show more irregular variations, but on the whole a decrease is shown of the same order in percentage as that of breaking load. (The extension of the waste yarn was particularly irregular, as specimens often extended considerably between maximum tension and complete rupture.)

Lea Test

Mounting of Specimen—A great difference in the evenness of tension and gripping of the threads may be made by the manner of placing the lea on the hooks. To estimate the possible variations, comparison tests were carried out on leas wrapped from the same cop and placed in six different ways. (1) *Ribbon*—The lea, spread evenly on a wrap reel, was transferred carefully without allowing the threads to touch or overlap. (2) *Normal*—The wrapped lea was held at both ends to prevent twisting. (3) *Band*—The lea was held at one end only, and straightened by running a finger along it before placing. (4) *Half-twist*—The two ends of the lea were placed on the hooks from opposite sides, i.e., to give one longitudinal half-twist. (5) *Half-hitch*—An extra turn was given over one hook, two parts of the band overlapping. (6) *Unequal Tension*—The last ten of the eighty turns were $1\frac{1}{2}$″ less in circumference. The mean strength by method (1) on 14 cops of 20's Indian yarn was 61·2 lbs., and the mean ratios between the results by each method, and that of method (1) were—

Ribbon	Normal	Band	Twist	Half-hitch	Unequal Tension
100	$101 \pm 1{\cdot}7$	$115 \pm 2{\cdot}6$	$108 \pm 3{\cdot}1$	$108 \pm 2{\cdot}3$	$86 \pm 1{\cdot}7$

In the last, the 20 tight threads (12·5% of the lea) break or slip without contributing to the final load (14% less than that of the lea), but give enough friction to allow the remainder to show its full strength.

The first five results illustrate well the effect of increasing friction. The second type of lea is drawn by the tension into a ribbon similar to the first and shows no significant difference. In the third, many threads overlap and grip each other rigidly towards the end of the test, greatly increasing the portion (B) of the load. In the fourth and fifth the friction is further increased, but now to such an extent that the tension cannot distribute itself in the earlier part of the test, thus decreasing the portion (A).

The comparison between ribbon and band was repeated on a gassed 60's West Indian yarn. The mean of 20 values of the ratio was $112 \pm 0{\cdot}9$. Method (3) is probably closest to ordinary practice, but it gives the worst conditions, for the added load is a chance thing, incapable of control or interpretation as a yarn quality.

Whilst careless mounting increases the fiiction between the threads, this may be further diminished by testing smaller skeins. Leas, half-leas, and quarter-leas were wrapped in rotation from a cheese of 60's West Indian yarn to a total number of 72 of each size and tested, by method (2), with the following result—

No. of threads ...	160 ...	80 ...	40
Mean breaking load ...	42·3 ...	19·1 ...	8·86 lbs.
Ratio per lea	100 ...	$90{\cdot}4 \pm 0{\cdot}7$ ...	$84{\cdot}4 \pm 0{\cdot}9$

As the strength should *decrease* with length, and the break is slower for the full leas, the friction on the hooks of 80 turns is responsible for a considerable addition of load, even when the mounting is careful. By observation, no addition of load occurs after the first break in a quarter-lea, but a decided increase with full leas, although direct quantitative measurement of the portion (B) could not be made with precision.

Yarn Properties—Many attempts have been made to find some relation between observed "lea ratios" and various properties of the yarn. Smith[6] states that the ratio is greater for low twists, which may be due to the effect on extensibility or surface friction, and to the fact that the highly-twisted yarns are generally the stronger. The factors that may affect the chance process of breaking and slipping are so complex, and the empirical relations so irregular, that there is no hope of improving the significance of the test as it stands by such observations. It can only be given definite meaning by a logical analysis and by bringing it into relation with calculable and reproducible conditions.

Three cases of such conditions may be distinguished—(*a*) a long continuous thread in which the tension remains uniform, (*b*) a set of threads gripped at the ends so that the extension is uniform, (*c*) the same but slipping after the first break. The degree to which an actual test approximates to one or other of these cases depends on the friction at the hooks.

Using a full lea with threads overlapping, the test makes a rough approximation to (*b*). The portion (B) of the load after the first break is not, however, that given by the theoretical condition, but varies with the speed, the number, roughness, and extensibility of the threads and the manner of mounting. Even if the threads are held in a positive grip, the maximum load is not related to thread strength as simply as in the other two cases (see further, Paper V.), and there are more practical difficulties. Trial

tests gave erratic results owing to a kind of tearing, the distribution of tension among the threads depending on the position of the threads first ruptured.

Cases (*a*) and (*c*) give a simple relation. The "lea ratio" is less than 100 by v times the irregularity; where v is the same factor as before and the irregularity, the mean deviation as a percentage of the mean, is for (*a*) that of the breaking load, for (*c*) that of the extension. As the manner of break depends on the friction between the yarn and the hook, measurements were made of this which are described in Appendix I. The coefficient of friction is 0·15 and the ratio between the tensions on two sides of a half turn over the hook which the friction can maintain is about 1·6. This is not sufficient to maintain any appreciable differences of tension at the beginning of a test, i.e., when all the tensions are small, provided the lea is wrapped evenly without overlapping, nor to allow an increase of load after the first threads break. On the other hand, the differences in tension developed by differences in the load-extension ratio are insufficient to cause slippage, so that the actual conditions of the test can be made to approximate very closely to case (*c*).

In such a case the portion (B) of the load is reduced to insignificance, and the portion (A), the whole result, gives a "lea ratio" depending only on the irregularity of extension and the factor v, which is 3·38 for 160 threads. The mean deviation of the extension will be $160^{-\frac{1}{5}}=0{\cdot}36$ of that of the breaking extension of single threads and the irregularity of lea strength the same as that of lea extension as the variation of the mean ratio of load to extension over batches of 160 is negligibly small.

Results obtained on several yarns are given in Table II. with the calculated and observed ratios between single-thread and lea tests. A very large number of observations would be necessary to fix the lea ratio and the mean deviation of extension accurately enough to test a statistical theory. but these results are sufficient to show that the calculated load at first break is of the same order but rather less than the observed lea strength. The irregularity is not significantly different from that calculated. The lea test has not the statistical significance of 160 single-thread tests, but of 8 only.

Table II.

Comparison of Single-Thread and Lea Strengths.

Sample	Lea Test			Single Thread Test					Lea Ratio		Lea Irregularity Calculated
	No. of Tests	Lea Lbs.	Irregularity	No.	Thread Oz.	Irregularity	Extension %	Irregularity	Observed	Calculated	
60's West Indian ...	10	37·5	6·4	200	4·81	10·4	3·8	8·0	78	73	4·0
36's Sakel ...	20	106·8	3·9	277	12·69	7·3	7·0	6·5	84	78	3·0
32's American	20	62·8	3·5	200	6·94	8·1	5·9	7·2	90	76	3·4
20's Indian	32	64·5	4·6	160	8.48	10·3	5·6	9·0	76	70	4·1
20's Waste ...	8	63·2	3·2	200	8·30	19·9	6·0	12·9	76	56	8·2

The conditions of case (*a*), which give the simplest relation to single-thread strength, could be realised by winding thread over a number of small independent pulleys, a method only practicable for a dozen or so strands. The lea test as it stands can best be improved by testing quarter-leas as untwisted ribbons at half the usual speed, when the portion (B) is eliminated and the conditions of case (*c*) realised.

APPENDIX I.

Yarn and Hook Friction

When a thread passes over a cylindrical bar, in contact over a semi-circle, the friction just equals the difference of tension when the ratio of the tensions on either side is a constant which depends on the frictional co-efficient of the thread and metal. If the thread just moves under a tension T_1, and the opposing tension be T_0, then

$$T_1/T_0=e^{\mu\pi}=a$$

where μ is the coefficient of friction.

T_1 and T_0 were measured directly by hanging two pans on a thread passing over the upper brass hook of the lea tester, and adding lead shot one by one till movement just persisted. By loading each pan alternately a series of values was obtained with increasing tension.

A quicker method, involving both hooks of the tester, is to tie one end of a thread to one of the hooks and pass it several times round the hooks, suspending a known weight from the other end. If the load be T_0, and the lower hook be traversed at a constant speed, the force on the upper hook when the load is being raised is

$$T=T_0(1+a+a^2+\cdots\cdots\cdots),$$

the number of terms being equal to the number of threads, and

$$T=T_0(1+\frac{1}{a}+\frac{1}{a^2}+\cdots\cdots\cdots)$$

when the load is being lowered. A large number of values of a can be quickly obtained with different loads and numbers of turns. The force on the upper hook is measured on the dial of the tester, the bob and pawls being removed from the pendulum.

Using these methods on six threads of 36's Sakel, a mean value of 0·153 was obtained for μ. A value of 0·151 was obtained on 20's waste yarn and of 0·153 on 60's West Indian. The value is that between brass and the surface of the cotton hair, and is independent of the structure of the yarn. The value of a corresponding to $\mu=0·152$ is 1·61.

APPENDIX II.

In a paper published recently[3] some data on hank tests of wool are given, with the number of strands varying from 1 to 128. They show excellently the drop of breaking load due to variability of extension, from 1 to 32 threads, after which the mutual support of the more numerous threads introduces the additional load (B) and a slight rise. Table III. shows the data (Table A, *loc. cit.*) fitted to the formulæ of the theory used above. When the breaking loads are fitted for 1 and 32 threads, a very probable value is given for the irregularity of extension and the formula fits the earlier observations, falling below them for the 128 strands. The standard deviations follow the $r^{-\frac{1}{2}}$ series, with which they are compared, as closely as the number of tests would allow.

The conclusion drawn by the observer[2] that the rise for larger hanks is desirable, and gives a closer approximation to the "true" value as shown by single thread tests is the very reverse of the real meaning of the curve, for the fall is significant and calculable, the rise adventitious and of no useful meaning. It appears to vary widely even among the three yarns of this table, being less for the smoother worsted yarns.

The decrease of strength when the hanks are clamped could not possibly occur if the initial tension were uniform and the specimen loaded evenly, but agrees with the experience in this laboratory. A sound test cannot be hoped for along that line.

Table III.

Variation of Strength per Thread with Number of Threads.

Yarn	Threads	Tests	Breaking Load ÷ No. of Threads Observed	Breaking Load ÷ No. of Threads Calculated	Standard Deviation Observed	Standard Deviation Calculated
			gms.	gms.

29—VII.—TENSILE TESTS FOR COTTON YARNS
ii.—THE BALLISTIC TEST FOR WORK OF RUPTURE

By Edward Midgley, B.Sc., and
Frederick Thomas Peirce, B.Sc., F.Inst.P.
(British Cotton Industry Research Association)

INTRODUCTION AND SUMMARY

There is no doubt that, other things being equal, an improvement in spinning or in the quality of cotton and in the resulting yarn quality will usually be shown in an increased breaking load of the yarn. In the more general uses of testing, however, the latter is not a direct measure of useful strength, for the test is so far removed from the strains which are liable to injure a yarn in practice. These are rather in the nature of sharp plucks, and the quality needed in the yarn is the ability to stretch without injury as well as to stand a definite load.

Tendering usually diminishes both the breaking load and the extension, but some treatments increase the load while decreasing the extension, in which case it will probably be found that the yarn is, for practical purposes, tendered. As an example, it was found that a dyed yarn broke every few yards in dressing, though the grey was of good strength. The dyed and grey yarns were compared by single-thread and by the ballistic test to be described, one set of results being shown here—

	Breaking Load, ozs.	Extension %	Ballistic Work
Grey	$4{\cdot}84 \pm_{.07}$ ...	$4{\cdot}17 \pm_{.11}$ ...	$111 \pm_{3.4}$
Heliotrope ...	$5{\cdot}63 \pm_{.09}$ ...	$3{\cdot}21 \pm_{.07}$ ...	$98 \pm_{1.2}$

According to the breaking load, the yarn had been considerably strengthened by dyeing, but the dresser knew, what the ballistic test showed, that it was seriously tendered, owing to the loss of extensibility.

The most complete test for the tensile properties of a yarn is to find the relation or curve connecting the extension and the load at each moment from the beginning of tension to rupture. Examples of such curves, which are given below, show that extensibility alone is a very uncertain guide to quality, for unresistant, inelastic extension is of little value. This is shown by the curves of a yarn when first straightened, the plastic flow of Celanese near rupture or the slow pulling out of yarn spun to too high a count for its staple. Real quality is shown by extensibility combined with a resisting tension. The work or energy absorbed in rupturing a yarn is the sum of each increase of length multiplied by the tension producing it. If the ratio of extension to tension remains the same, this work of rupture is $\frac{1}{2} \times$ breaking load $\times$ extension. This is very approximately the case for sized yarns; with unsized yarns the extension is less resistant at low tension than near rupture, and the factor is rather less than $\frac{1}{2}$; with artificial silk,

the extension is more resistant at low tension and the factor is more than ½. Work of rupture is thus a measure of combined strength and extensibility which takes into account the behaviour over the whole range up to rupture.

Whilst a thread will suffer the same extension to a very close approximation whether broken slowly or rapidly, its resistance and final breaking load increase considerably with the rate of loading (Paper III.). The test should therefore be performed as nearly as possible at the same speed as the strains encountered in practice, which are undoubtedly not slow steady extensions but rapid jerks. Fortunately, the work absorbed in a rapid break is capable of convenient measurement by the ballistic method. This test is being used increasingly on metals and other materials, but in no field are its advantages so decided as in textile testing. The earlier applications of the principle and its possibilities are discussed in a previous communication,[5] the work of Lester[4] being the first and especially noteworthy. Denham[2] has recently used the test on silk thread, and the principle has been applied to testing cotton hairs by Balls[1] and Foster.[3]

The Ballistic Tester

The tester described below has been developed with the object of providing a test as convenient as those in vogue for commercial purposes, while giving a result of exact and scientific meaning. It is introduced on the grounds that the quantity measured is the most significant single measure of yarn strength, but its use might equally be justified from the viewpoint of testing routine. The breaking load must be measured laboriously on single threads, or accuracy sacrificed in breaking a skein of which the apparent strength depends on the order in which the individual strands break. The ballistic tester measures the total amount of energy absorbed, which is unaffected by the order of breaking or the number of threads.

Work, mechanical energy, is performed when a point is moved against the resistance of a force, e.g., in the extension of a yarn against its tension or the raising of a body against its weight. In the latter case, the work reappears as energy of movement when the body is dropped. This kinetic energy can be used to extend and break a yarn or lea of yarn. In the ballistic tester (Fig. 1) the falling body is a heavy pendulum (A) which is released from a known height. If no work is done in the swing, the pendulum rises to the same height in its upward swing. If it is made to break a specimen (B) it rises to a lower height and the difference between the two heights gives a measure of the energy absorbed in rupture.

The fixed anchorage (C) is placed so that the specimen becomes taut when the bob is about 1 in. from its lowest point, and it can be adjusted for lengths of yarn from 10 in. to 30 in. The specimen is fixed in two small detachable grips, of which a number are kept at hand, by two serrated plates screwed together. These are hooked over round bars on the anchorage and at the point of percussion of the pendulum. The releasing catch (Fig. 2) engages a square bar on the pendulum automatically when the latter is pushed against it. It can be moved to any height on an arc (D) with no more trouble than the turn of a thumbscrew. The height to which the pendulum rises is recorded by a light aluminium pointer (E) held stationary by the light pressure of a pawl on the top edge of the recording arc (F). Both arcs are graduated in equal intervals of height which in the present instrument are 1/10th and 1/100th of the radius, but could as easily be made to correspond

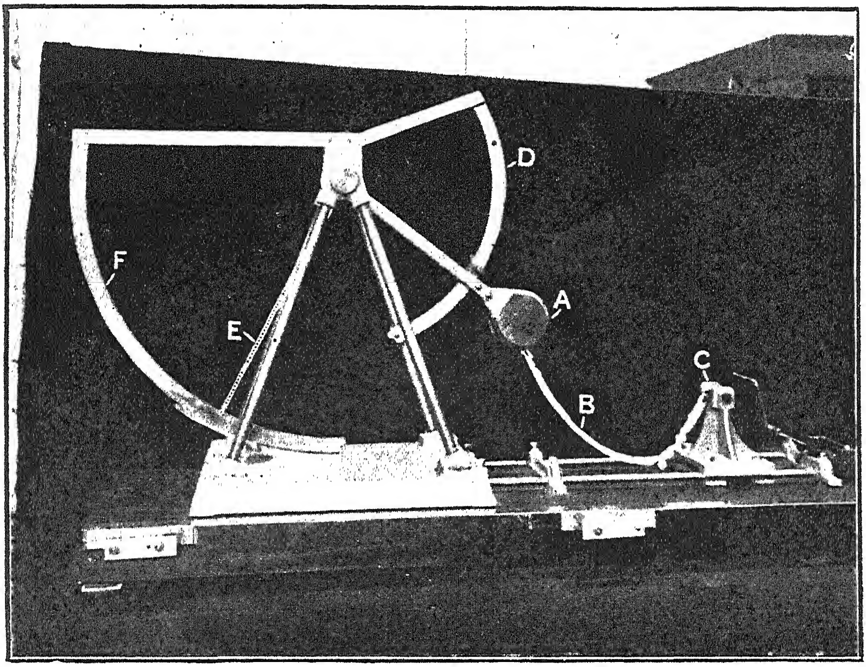

FIG. 1

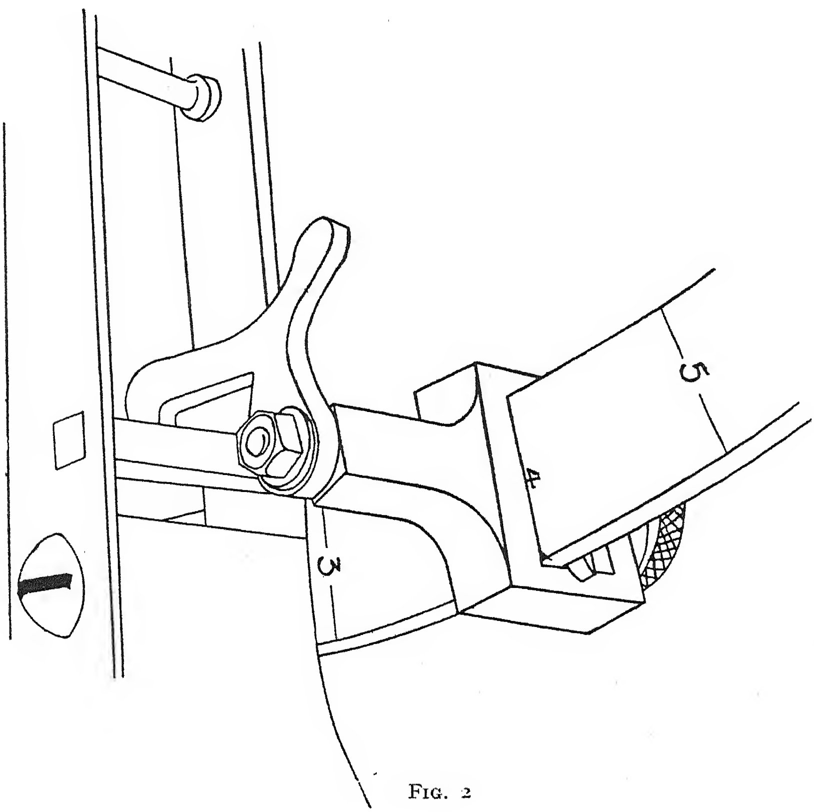

FIG. 2

to absolute units of energy.* The bob is fastened by two stout bolts so that the capacity can be varied by replacing it with a heavier solid bob or a lighter aluminium one.

Apart from questions of convenience, the essential feature of design is that no appreciable energy should be expended except in breaking the specimen. The grips and their anchorages must be rigid, so that they only yield by an amount negligible in comparison with the extension of the specimen. The frame and supports for the pendulum must also be rigid and the axle frictionless (in ball bearings). Furthermore, the pendulum must be designed to resist the impact, to minimise air resistance, and for proper balance, so that the grip can be fixed at the "centre of percussion." As in a cricket bat there is a point where the ball can hit without jarring the hands, so if the impact comes at the correct point on the pendulum, the whole weight acts as if concentrated at the grip and there is no impulsive force on the support or bending moments in the pendulum.

Before a series of tests the releasing catch is fixed so that the swing is sufficient to break comfortably the strongest specimen. A mean reading of 0·3 is sought, as this is in a sensitive part of the scale and ensures approximately the same velocity of the bob, i.e., rate of extension, at break for all tests. For testing leas, the yarn is wound on a wrap reel and the grips fixed at opposite diameters. The routine of a test consists in slipping the grips into position, pulling the releasing trigger, taking the reading, and swinging the bob back to the catch, which occupies in all perhaps five seconds, apart from the time required to fix the grips on the specimen.†

As the result of the test is the sum of the work absorbed by each thread, it should be proportional to the *number of threads* within the limits allowed by the variability of the yarn. By observation on specimens from 10 to 80 threads (Fig. 3), the work per thread was found to be constant and therefore equal to the mean work of rupture of a single thread. Among the consequences of this simple relation, the irregularity of results should decrease as the square root of the number of threads, this also being borne out by the observed figures. From lea tests on 17 varieties of cotton yarn, the mean irregularity of work was 3·46%, of breaking load or "pull" 4·56%. The ballistic test gives the more regular results, although they involve variations both of breaking load and extension, because the mean deviation of skein strength decreases very slowly, as the 1/5th power, with number of threads (*vide* Papers I. and IV.).

It is no small advantage that accurate comparison should be possible between specimens of different numbers of threads, for this is tantamount to a greatly extended range. A single or double tyre cord, a few strands of

* The C.G.S. unit is the erg or the joule (10^7 ergs) or the gramme.centimetre. The latter is most convenient for research purposes, and is the work done in raising one gramme one centimetre. The English engineering unit is the foot.pound, but for textile testing one-twelfth of this, the inch.pound, appears very suitable as it gives a figure for leas close to that given by the usual lea test, and because the extensions are of the order of an inch. The full capacity of the instrument is 80 in. lbs., or 92,170 gm. cm., that is, it will just break a specimen which will just bring to rest a weight of 80 lbs. in a fall of 1 in., or 40 lbs. in a fall of 2 inches.

† In a later model, grips are dispensed with for lea testing, the skein being hitched to a bar at either end. The complete routine is then distinctly quicker than the usual lea test. (2nd June 1926.)

sewing cotton, a lea of 50's and a double lea of 100's can be tested and compared, the total work of each being approximately the same and close to the capacity of the one instrument.

The variation of breaking load with *speed of break* is described in Paper III., and this effect may be expected to increase the work of rupture if a weak specimen is broken by the full fall of the pendulum. The results (*loc. cit.*) show a slight tendency to rise, perhaps 2% between readings at 0·2 and

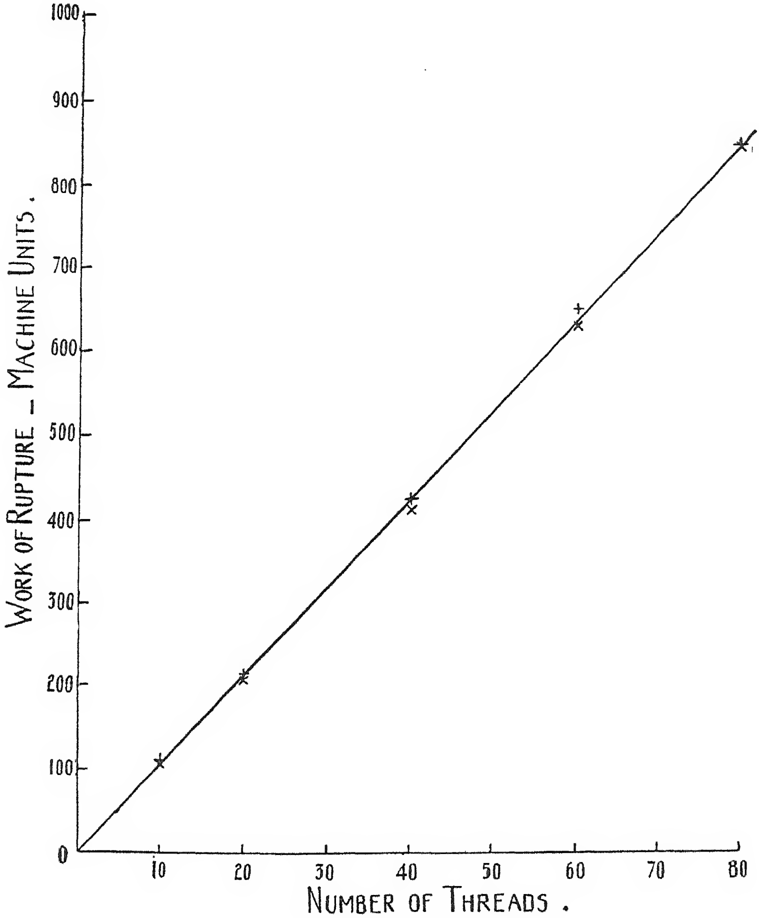

Fig. 3

0·6 on the scale graduated in fractions of the total capacity. In ordinary use the release is set to give readings always in the region of 0·3 to ensure a clean break and a sensitive scale. This also fixes the final rate of extension of the specimen, avoiding the effect of speed on breaking load, and giving the fairest comparison between materials of different strength and elasticity.

Comparison between the ballistic results and single-thread properties measured in other tests is mainly conditioned by the relation between breaking load and speed, and is made clear by a consideration of autographic load-extension curves (see below) and by the experiments described in Paper III.

The work of rupture is not exactly proportional to the *length of specimen*, but becomes so by subtracting a small constant amount. The relation is fully accounted for by the decrease in breaking load with strength owing to irregularity, as found in Paper I., together with a smaller effect due to the more rapid break of short specimens. The energy absorbed at the point of rupture in pulling the hairs apart seems too small to have a measurable effect. For routine testing the length of specimen should be kept constant for the same reason as in single-thread testing, the irregularity along the length.

While designed primarily for testing skeins of yarn as wound on a wrap-reel, the ballistic tester can be used equally well for single tapes of yarn, thus facilitating the use of the "*cut-skein sample*" method. Control tests show a striking degree of identity between sets of halves and such samples are used regularly and confidently for isolating and measuring very small effects in tendering by light or acids, &c.

The rapidity of the test allows the testing of yarns in a state which cannot be maintained for more than a few moments, e.g., bone dry. It is therefore particularly suitable for use in conjunction with the humidified box where a controlled room is not available. The specimen, previously fixed in the detachable grips, can be removed and tested before any change in moisture condition can occur.

Very regular results have been obtained on cords, tapes, strips of duck and wires, the only adaptation being a special form of grip if necessary. In a set of 12 tests on single copper wire the maximum variation was from 84 to 93 units, though the total energy absorption was not one-tenth the range of the instrument. As a routine test for artificial silks, this method avoids the long plastic flow which detracts from the value of measuring breaking load and extension at slow speeds.

The machine comprises a heavy pendulum mounted on ball bearings, with a scale and pointer to record its maximum deflection. It is therefore essentially of the same construction as a standard *lea tester*. A semi-circular pulley is fixed at the axis to strengthen the pendulum and to assist in obtaining the proper balance or position of the centre of percussion. This also serves as a pulley over which a flexible strip with a lea tester hook can be affixed in a second (Fig. 4). A winding apparatus with lower hook is permanently fixed at the end of the stand, and can be operated either by hand or motor. The results are identical with those of an ordinary lea tester.

Expressed in inch-pounds the ballistic work of a lea is usually a fraction greater than the "pull" in pounds, but the fraction is variable, as the latter is subject to the many disturbing factors not affecting the work. Its relation to single-thread breaking load depends not only on the extensibility and on the shape of the load-extension curve, but also on the effect of speed, which may vary according to the yarn. Roughly the results by the different tests are of the following relative order—Single-thread, 6 oz. (60 lbs. per lea); Moscrop, 7·5 oz. (75 lbs. per lea); lea test pull, 44 lbs.; ballistic work, 55 inch.lbs.; but they cannot be calculated one from the other.

The ballistic tester described above has been in regular use in this laboratory since the beginning of 1924, and has proved in practice a thoroughly trustworthy and convenient instrument for routine testing. A model, even more serviceable and simple in construction and operation, is at present under construction.

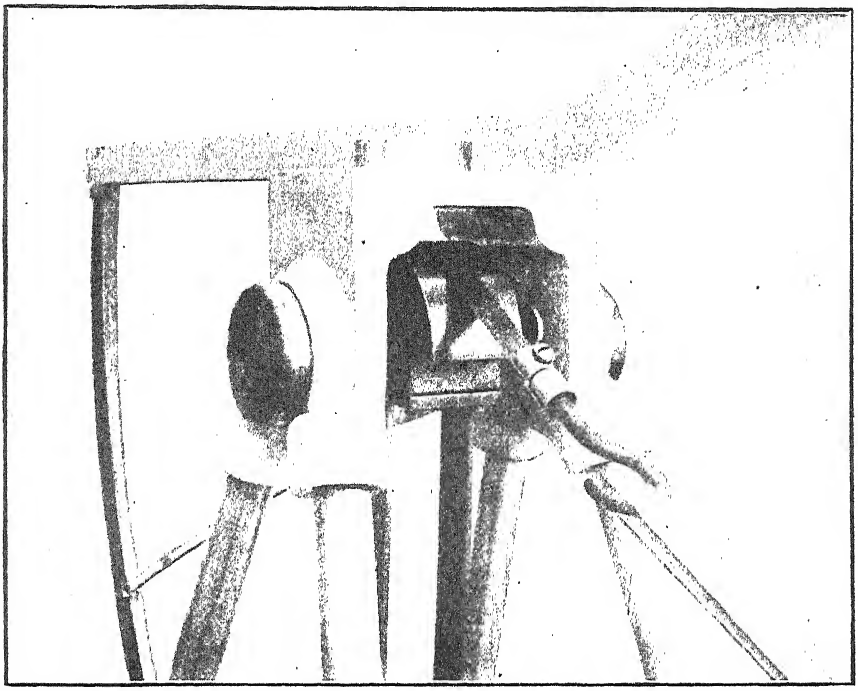

FIG. 4

Load-Extension Curves

An understanding of the quantity, work of rupture, which is measured in the ballistic test, and of the relation between this and single-thread tests, may best be obtained by a study of curves of load against extension. They also provide another method of measuring work of rupture and have great use in research, as distinct from routine testing, on unfamiliar kinds of thread, especially in conjunction with the ballistic tester.

Several instruments have been described or manufactured for tracing such curves, most of which are complex and have mechanical magnifying devices which introduce forces too large in comparison with the light load on a yarn. The simplest and soundest for yarn testing appeared to be that described by Shorter and Hall,[6] which has the great advantage of being usable at high speeds. In Fig. 5 a modification of their instrument is illustrated, designed for testing cotton yarns. The lower grip is made adjustable for lengths up to 25 in., and the record is made by a gramophone needle on a smoked glass plate. (The record of a fine pen on a polished card is not much coarser, and is quite satisfactory for most purposes.) The upper grip is fixed to the spring by a very light frame of duralumin. A steady rate of loading is obtained by attaching the carriage to the piston of a single-thread tester, but it may be driven also by hand, motor, or falling weights. Otherwise the principle of the machine and the diagrams are as described in the paper cited.

A few examples will show the use that can be made of these load-extension curves. Fig. 6a shows the trace given by a strand of nickel wire. The horizontal line is that traced when no specimen is mounted and marks

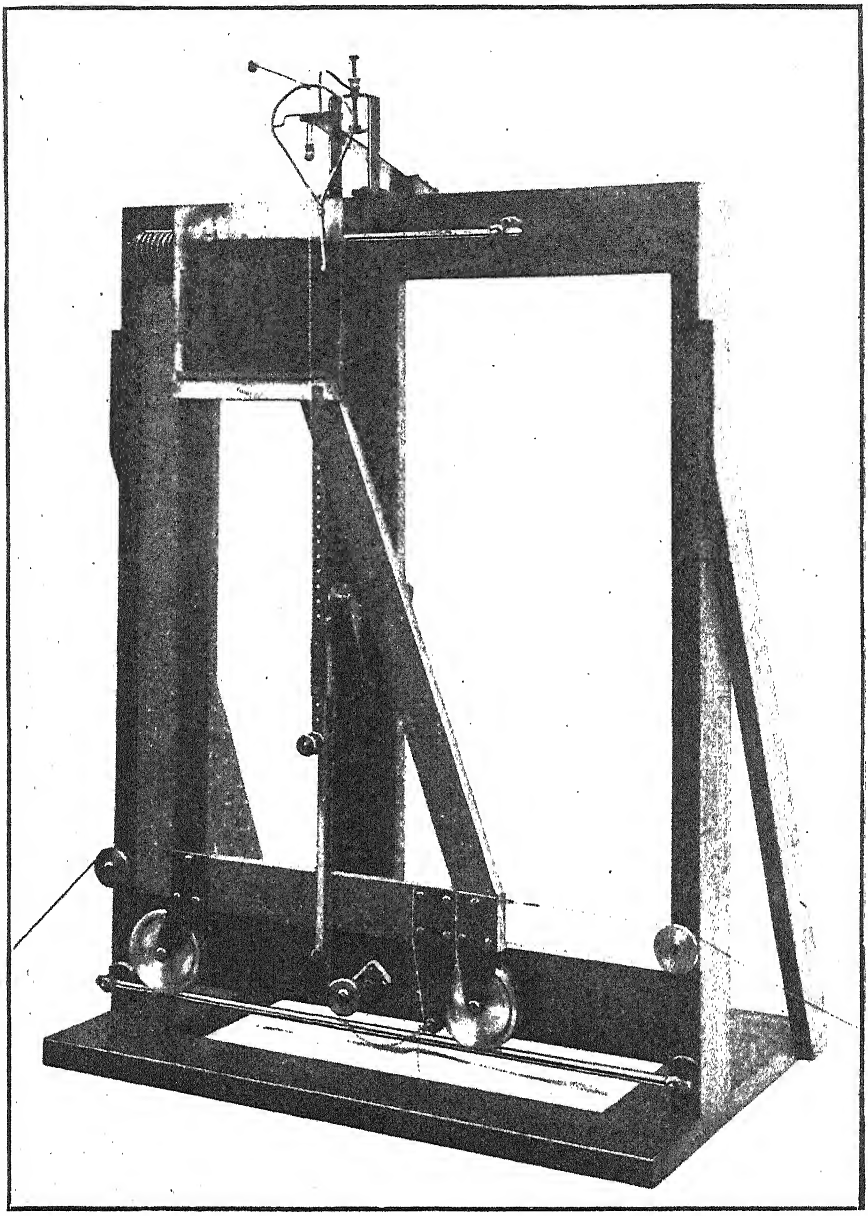

Fig. 5

the zero of tension, the line at 45° to it is traced when the grips are connected by an inextensible specimen, a metal chain, and marks the zero extension. On the trace given by the nickel wire the vertical distance from the first measures the tension, the horizontal distance from the second the extension. In Fig. 6b, the trace is redrawn so that the horizontal distance from the origin is equal to the extension, i.e., in rectangular co-ordinates. This curve is typical of most simple materials. At first the trace is straight

and the extension is proportional to the load, independent of time, and perfectly elastic. Then, at the yield point, it increases more rapidly, and in this region the specimen would extend without further load and would retain some extension if unloaded.

Fig. 7, traces given by Celanese and viscose, shows that artificial silk follows a similar course, but the latter "plastic" portion is longer, and the elasticity is not so truly perfect in the straight portion. On Fig. 8 are compared traces of 36's Sakel yarn, sized and unsized. Fig. 9 shows that of a yarn, spun to counts too high for the quality of the cotton, which broke by pure fibre slip instead of snapping like an ordinary yarn. The varying form of these curves shows how differently materials may behave under tension and the very limited information given by measurements at break alone.

The resistance of a cotton yarn to extension is shown more clearly by Fig 10. The simple trace A is that given by a 36's Sakel yarn loaded steadily to rupture, the other of a similar yarn put through a more complicated operation. At low tensions the trace is slightly concave, the resistance increasing as the twisted fibres straighten and press together. Under steady loading it then becomes straight till the thread breaks, but, as the second trace shows, this straight line does not mean truly elastic extension as in metals, but depends on the steady rate of loading. At B the carriage was held still and the thread continued to extend under a decreasing load. On releasing the tension, it was found that a large portion OC of the extension remained, part of which was permanent, whereas part was slowly recovered from, for after a few minutes rest tension began again at D. Increasing the tension steadily again, the yarn passed through its former state at B, and then behaved in the same way as the first yarn loaded steadily. At E the tension was kept constant, but the yarn continued to extend slowly and appeared to come to rest. Further tension was added and again maintained constant at F. The yarn continued to extend for about a minute, when it broke at a load much less than the breaking load of the first, but with an extension not appreciably different.

On Fig. 11 are the traces given by two threads loaded steadily, one very slowly, one quickly, the breaks occupying 100 and $\frac{1}{3}$ sec. respectively. The latter has a lower breaking load, but the final extensions are nearly the same. A change of breaking load with speed is thus a real property of the yarn, while no evidence could be found (Paper III.) of any significant change of final extension.

In Fig. 12 each little figure made by the shading is equal to the product of a portion of the extension, and the tension producing it, whilst the whole shaded area gives the work of rupture. The area increases as the speed is increased, for example, the work of rupture of a 36's Sakel yarn in gram. cms. per cm. was 9·7 at slow single-thread speeds, 12·2 at Moscrop speeds, while the faster ballistic test gave 14·7.

The work of rupture may be expressed as a constant factor multiplied by the product of breaking load and final extension. The factor is 0·5 if the trace is a straight line, and for unsized single yarns it is usually between 0·5 and 0·4. The factor for a batch under test can be obtained from 10 load-extension curves, and the work of rupture then calculated from the mean product of load and extension found on the deadweight tester. The advantage of this is that the test on the Shorter and Hall instrument is

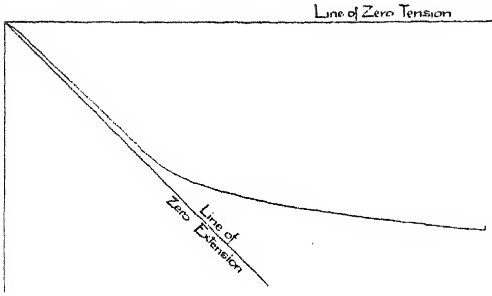

FIG. 6A

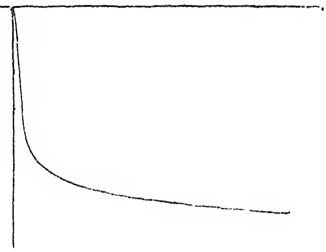

FIG. 6B

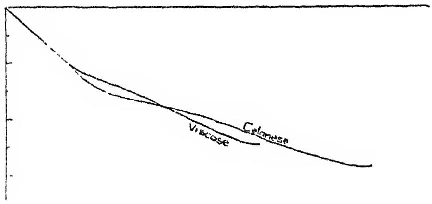

FIG. 7

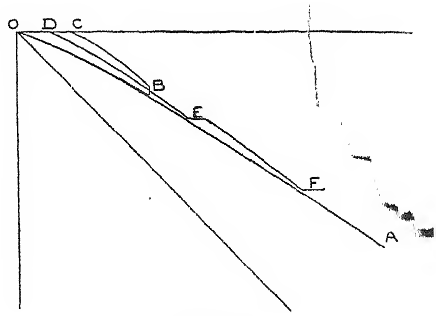

FIG. 10

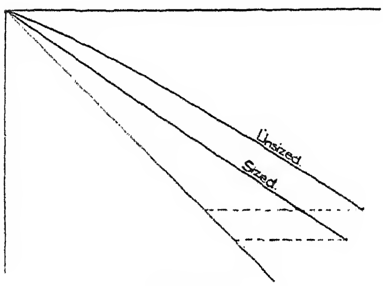

FIG. 8

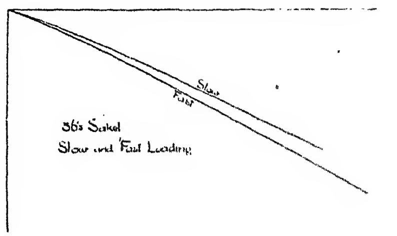

FIG. 11

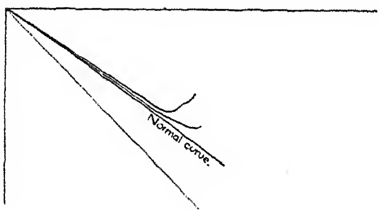

FIG. 9

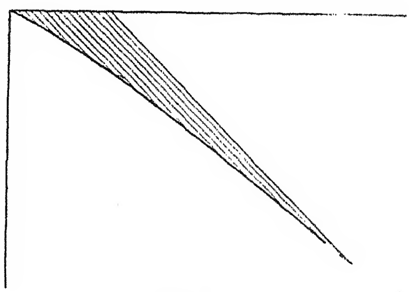

FIG. 12

slow and laborious compared even with the usual single-thread test. Autographic tests at high speeds may also be used to obtain a value for the extension and "work factor" from which to calculate the breaking load at ballistic speeds, and the several tests thus check and complement each other.

DETAILS OF EXPERIMENTS WITH THE BALLISTIC TESTER

The dynamical principles of the instrument are analysed in Paper IV.

Number of Threads

The proportionality between work of rupture and number of threads was tested on two sets of specimens of 80, 60, 40, 20 and 10 threads, with the results shown in Table I and Fig 3.

Table I.

Work of Rupture of Varying Number of Threads.

36's Sakel yarn, 26·5 inches in length. Reading in 1/1,000th of machine capacity.

No. of threads ...	80	60	40	20	10
Release	1,100	900	700	500	400
Reading—					
1st set of 20 ...	$245 \pm 5{\cdot}0$	$264 \pm 3{\cdot}3$	$283 \pm 2{\cdot}2$	$294 \pm 2{\cdot}0$	$294 \pm 0{\cdot}9$
2nd set of 20 ...	$243 \pm 3{\cdot}8$	$245 \pm 3{\cdot}5$	$273 \pm 3{\cdot}1$	$286 \pm 1{\cdot}6$	$290 \pm 0{\cdot}6$
Gm. cm. per thread—					
1st	$985 \pm 5{\cdot}8$	$977 \pm 5{\cdot}1$	$961 \pm 5{\cdot}1$	$950 \pm 9{\cdot}2$	$977 \pm 8{\cdot}3$
2nd	$987 \pm 4{\cdot}4$	$1006 \pm 5{\cdot}4$	$984 \pm 7{\cdot}1$	$986 \pm 7{\cdot}3$	$1014 \pm 5{\cdot}1$
Mean	$986 \pm 5{\cdot}2$	$992 \pm 11{\cdot}1$	$973 \pm 9{\cdot}9$	$968 \pm 14{\cdot}7$	$996 \pm 14{\cdot}4$

The work of rupture of the specimens is proportional to the number of threads, for the work per thread shows no consistent variation with number, nor are the differences of statistical significance but due to sampling variations alone.

As the result is a simple sum, its irregularity should decrease as the square root of the number of threads. The irregularity of the product of breaking load and extension was found on the 30-in. specimens of Table II., Paper I., to be for single threads, 12·4%; for the mean of 10 threads, 4·1%; and for the mean of 80 threads, 1·4%. In the above results it is for 10 threads, 4·2% and 2·6%, for 80 threads 3·0%, and 2·3%, which is as near as sets of 20 results could be expected to give.

Length of Specimen

The work of rupture will not be exactly proportional to the length of specimen for the following reasons—

(1) The breaking load decreases with length owing to irregularity, and the extension decreases in the same proportion.

(2) The time occupied in stretching to rupture increases in proportion to the length.

(3) The work absorbed in pulling the hairs apart and breaking them at the actual point of rupture is a constant addition to the energy absorbed in stretching the whole length.

All three make the work on shorter lengths proportionately greater.

The effect was measured on 11 in. and 30½ in. specimens of the 36's Sakel yarn, one of each being cut from a skein of 30 turns. The results obtained on 25 of such pairs and on 24 specimens of 24 in. length wound alternately are shown below—

Length	11 in.	30½ in.	Difference	24 in.
Gm. cm. per thread	483 ± 2	1126 ± 5	643 ± 4	917 ± 5
M.D.	13	31	26	26

These three points lie very exactly on a straight line, giving the work as a small constant amount added to an amount proportional to the length. The pairs define this relation for the work in gm. cm. per thread of length L cms., as

$$W=119{\cdot}6\ (\pm 0{\cdot}3)+L.13{\cdot}0\ (\pm 0{\cdot}1).$$

For the 24 in. length this gives 912 ± 6, which is statistically the same result as that observed, and 994 for the $26\frac{1}{2}$ in. length, in good agreement with the results on Table I.

The constant amount, 119·6, is equivalent to an extension of 4·6 cm. at the maximum tension, and if the last effect (3) were responsible for the whole amount, it would mean that a resistant extension of this order occurred at the place of rupture. The load-extension curves show that this is not the case, and it is doubtful whether any appreciable energy is absorbed at the ruptured portion, for the first two effects are sufficient to explain the greater strength of shorter lengths. From the two sets of single-thread tests on 10 in. and 30 in. lengths of this Sakel yarn (Table I., Paper I.), the correction to the product of load and extension of 30 in. lengths necessary to make it equal to that of 10 in. lengths would be 0·4% and 19·9% respectively, the theoretical amount calculated from the irregularity being 19%. From the results given in Paper III., the correction for the trebled speed should be about 3·6%. As an addition of 18·9% to the work on the $30\frac{1}{2}$ in. lengths would reduce the constant amount to zero, only a small proportion of it can have the physical significance of work absorbed at the break.

Ballistic Machine Used as a Lea Tester

The following tests were performed on alternate windings of the various yarns with a standard lea tester and the ballistic machine used as a lea tester (Fig. 13). For this use the latter is as circumscribed in range as any other deadweight instrument, and 30 turns of the stronger yarns had to be compared with 40 turns on the heavier standard tester. This can be done by multiplying by 4/3, as the difference is not great enough to introduce the complications discussed in the last paper.

Tests on 10 specimens with each Tester. Breaking loads in Pounds.

Leas of 60's West Indian yarn:—	Half-leas of 36's Egyptian ring yarn:—
Standard $44{\cdot}2\pm 0{\cdot}8$, M.D. 6·2%.	$49{\cdot}5\pm 0{\cdot}4$, M.D. 3·2%.
Ballistic $44{\cdot}1\pm 0{\cdot}4$, M.D. 3·0%.	$53{\cdot}2\pm 0{\cdot}3$, M.D. 2·9%.
Half-leas of 36's Sakel yarn:—	Half-leas of 32's Egyptian yarn:—
Standard $53{\cdot}5\pm 0{\cdot}4$, M.D. 2·7%.	$52{\cdot}2\pm 0{\cdot}4$, M.D. 3·0%.
Ballistic $55{\cdot}9\pm 0{\cdot}4$, M.D. 2·7%.	$51{\cdot}1\pm 0{\cdot}3$, M.D. 2·0%.

As is to be expected, there is no significant difference between the results. If anything, the ballistic machine gives rather less variation, which may be a real difference, as the friction is less and the pointer stops dead.

Greater range can be obtained by replacing the bob with a heavier one or by affixing weights to the stem of the pendulum. Calibration is done conveniently by hanging weights and readings converted by a graph from the ballistic scale or taken directly from a deadweight scale on the reverse side of the recording arc.

It must be remembered that the results of such a lea test are of a lower order of accuracy than those of the ballistic method, and do not give a mean value of breaking load. In particular, they cannot be used in combination with the work of rupture to find the breaking load and extensibility separately except in a very rough, comparative way.

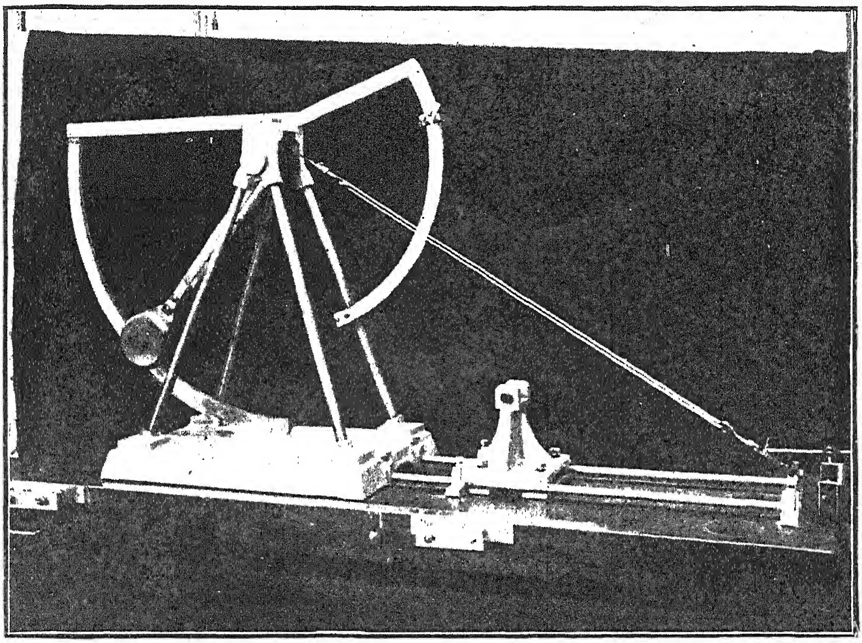

Fig. 13

Cut-Skein Samples

In a control test on 25 windings of 30 turns of 36's Sakel yarn, one set of halves gave a mean $313{\cdot}68 \pm 1{\cdot}14$ work units, the other $312{\cdot}44 \pm 1{\cdot}16$. The absolute differences between the corresponding halves were distributed thus—

Difference	0	1	2	3	4	5	6	7	8	9	10	11...15
Frequency	1	2	2	2	2	2	4	2	2	1	1	1... 3

As 15 of the 25 differences are 6 or under, the probable difference between two halves of one winding is under 2%. With specimens nearer the capacity of the instrument, 1.000 units, and more threads, the probable difference should be correspondingly diminished.

This test was done on a very regular yarn, but was repeated on one of the roughest and most irregular obtainable, a 20's waste yarn. On 50 pairs of "cut-skein samples" (30 turns), the mean of one set was $217{\cdot}62 \pm 1{\cdot}88$, of the other $217{\cdot}74 \pm 1{\cdot}99$, and half the differences were under 6, the distribution being—

Difference ...	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
Frequency ...	6	5	2	4	5	3	5	3	3	4	1	3	0	2	2	1	0	1

30—VIII.—TENSILE TESTS FOR COTTON YARNS
iii.—THE RATE OF LOADING

By Edward Midgley, B.Sc., and
Frederick Thomas Peirce, B.Sc., F.Inst.P.

INTRODUCTION AND SUMMARY

The necessity for operating a testing machine at a standard rate is generally recognised. This arises partly from instrumental errors introduced at high speeds, but when these are allowed for (*vide* Paper IV.), there is still a consistent and appreciable increase of apparent strength as the test is speeded up. In comparing the breaking loads of a yarn as measured on different instruments, the results are found to vary very greatly with the time occupied in a break. The Moscrop test, occupying about ½ second in stretching the thread to rupture, has been found to give a result usually between 20 to 30% above that of the standard single-thread test, which occupies about 20 seconds. The ballistic test breaks a specimen in about $\frac{1}{50}$th second, and the breaking load can be calculated, on assumptions which cannot be greatly in error, by dividing the work by one half the extension. The load so calculated was found on 23 different yarns to be on an average 43% above the standard load.

To measure with some precision the variation of breaking load of a yarn when only the speed of testing is altered, a very regular 36s Sakel yarn was tested on several instruments over the range of speed allowed by the mechanism, taking particular care to obtain similar samples and constant testing conditions. The apparent strength was then found to increase with the speed of the test in a definite and regular manner, the rate of change within the range of each instrument agreeing with the greater differences between the results of the several tests. The mean breaking load on the standard single-thread tester varied from 11·7 oz. to 13·0 oz. as the rate of traverse varied from 3 to 30 inches per minute. Taking the mean value when the specimen is broken in 20 seconds as 100, the breaking load given by the Moscrop tester, taking about ½ second, is 129; with a variation in time of break on the autographic instrument from 90 to 0·4 seconds, the value changes from 96 to 121; and the value calculated from the ballistic test, taking $\frac{1}{45}$th second, is 139. Further, one half the specimens broke within 2½ minutes under a load 72% of the standard value, within 92 hours under 58%, or within 18 days under 50%. Taken over all the range of speeds, the mean breaking load of the same yarn varied from 5·6 oz. to 18 oz., due solely to the change in the time occupied in the break, namely from a month to $\frac{1}{60}$th second.

These changes may be generally expressed in a very simple way, namely, that if the time of break is increased tenfold, the breaking load always

decreases by the same amount, $\frac{1}{10}$th the value given by the standard deadweight tester. Though the rate of change must become less, both for extremely slow and fast breaks, the relation remains constant over the range of practicable observation.

No change in final extension could be found on the deadweight tester, nor on the autographic instrument when the speed was altered 200-fold. It would seem that a yarn breaks because it is forced beyond a limiting extension, rather than because it is overloaded.

The relation with speed for the breaking load of a yarn is the same as that for hairs, i.e., the ratio between the breaking load of the yarn and of the hairs which compose it remains constant with speed at a value found to be 0·4 in this particular case. Moreover, there seemed no appreciable difference in type of break between ends broken ballistically or slowly. The conclusion thus indicated is that though the uniformity and clinging power of the hairs is only sufficient to make less than half the aggregate strength available, this factor does not alter with speed, and the load at rupture is determined by that of a core of tightly gripped hairs. Data[1] are quoted to show that the same effect in fabrics is of the same order of magnitude and may also be wholly or largely ascribed to the elastic properties of the hairs.[2]

As a matter of testing routine, speed is standardised by the rate of traverse of the loading jaw or by rate of loading. This eliminates mechanical errors but does not wholly eliminate the effect of speed on apparent strength, which is a function of the time occupied in the test. Results given by a strong and a weak specimen on one instrument are not strictly comparable, since the former is broken more slowly. The same specimen would appear a few per cent. stronger on a heavy instrument than on one of just sufficient range, both driven at the standard rate. Fortunately the effect is not rapid enough to demand attention in ordinary routine testing, but as the speed of testing and the resulting breaking load are arbitrary, it is preferable to approximate to the speed with which yarns are broken in practice. The greater rapidity of the ballistic test means a closer approximation to working conditions and also to the upper limit which must exist as an absolute strength characteristic of the material.

The effect should not be lost sight of when interpreting tests for wear, oscillating stress, &c., of which the results are expressed by the number of rubs or jerks survived, for a load less than half the deadweight breaking load will continuously extend the yarn towards rupture without the help of wear.

EXPERIMENTAL METHODS AND RESULTS

Each testing instrument is designed to work within a particular range of speeds, which is limited by dynamical considerations (*vide* Paper IV.) and by convenience of operation. One machine can be used only over a small portion of the total range of practicable speeds, and the variation of breaking load must be followed through several different tests.

The speeds of the several machines are controlled in different ways, and mutual comparison is facilitated by using the quantity T, "the equivalent time of the break," i.e. the time which would be occupied in loading the specimen to rupture at the rate of loading obtaining just before rupture. The formulæ for the values of T used below are worked out in the following

paper. It will be shown at a later stage that the breaking load (F) is most simply expressed as a function of log T, and the curve will be defined by evaluating for the small range covered by each instrument the slope ($dF/d \log T$), and the mean values of F and log T.

The tests were all carried out in a room maintained at 70° F. and 70% R.H. on a very regular 36s Sakel yarn. Wherever possible, comparisons were made by the "cut-skein sample" method (Paper I., p. 78), or on consecutive windings from the same cop.

Standard Single-Thread Deadweight Tester

The instrument used is driven by an oil plunger, thus avoiding the initial jerk and consequent oscillation (*vide* Paper IV.). The pendulum has a very short time of vibration (1·0 sec.), reducing momentum errors to a minimum, and the tester may safely be used over the range which can be obtained from the plunger. The speed is controlled by the fall of the lower jaw, the normal being 12 inches per minute, and tests were made in pairs at speeds from 3 to 30 inches per minute on sets of 50 alternate threads of 20 inches length.

The speed of fall, the time of break (from Equation 10b, Paper IV.), and the corresponding mean values of breaking load and extension for the seven pairs of tests carried out are shown in Table I. The probable error of the difference between any two values of breaking load, considering the samples as independent, is 4·0 grams, and a difference of less than 12 grams is hardly significant. Taken as a whole, the values show a regular and significant increase with speed. Those from pair No. 5, however, are far off the general range and give the only case of a decrease. As the sample is exceptional, the values are ignored in taking the general means. (The deviations of the breaking loads of this pair from the best straight line through the remainder are six times the probable deviation calculated from the other twelve values.)

Between the members of the pairs, the differences have a higher significance and are very consistent. Expressed against log T the mean slope of the six tests is 29·3 ± 5·1 grams; weighted according to the difference in log T, the mean is 25·7 grams. The slope given by the slowest (1a) and fastest (7b) breaks is 34·2 grams, and the median slope between the pairs is 30·4 grams, perhaps the best value as most independent of the method of expression. The best straight line drawn through the array of points by the method of least squares gives a slope 34·5 grams. (The correlation coefficient between F and log T is 0·84, and the probable variation of the slope is about 3·4 grams.)

There is no correlation between the extension and the speed among the independent samples. (The actual correlation coefficient between e and log T is + 0·067, which is not significant.) The differences within pairs show no regularity either of magnitude or sign, nor are they big enough to be statistically significant, but appear to be purely random variations of testing and sampling.

For the purposes of the general relation, the results on this machine will be expressed by a slope—

$$\frac{-dF}{d \log T} = 30{\cdot}4 \text{ grams from } \log T = 0{\cdot}94 \text{ to } 1{\cdot}91,$$

through the point ($\log T = 1{\cdot}33$, $F = 347$ grams), the extension remaining constant at 6·48 ± ·03%.

* $\dfrac{dF}{d \log T}$ is the symbol for the tangent or slope at a point on the curve.

$\dfrac{\Delta F}{\Delta \log T}$ is the symbol for the slope between two points separated by an appreciable distance.

Moscrop Tester

The breaking load can be measured at much greater speeds on the Moscrop tester, to the limit of speed imposed by the errors discussed in Paper IV. The speed is controlled by the number of complete cycles per minute, eight being normal. The equivalent time of break is given by Equation 27, Paper IV., in terms of velocity of the loading jaw ($\dot{x}$), which in the present work, with breaks occurring at the middle of the 32 oz. record, is 1·306 p, whence $T = 0{\cdot}217\ F/p$.

The correction for the fling of the pointer is also evaluated as 0·00406 p^2 oz., and is thus allowed for in Table II., where results of tests from 3·6 to 25 cycles per minute are given. The first seven tests were carried out in one day in immediate succession, 75 specimens on each of six cops at each speed, this being the nearest approach to alternate thread sampling for this machine.

The dynamical analysis and tests given in Paper IV. show that the speeds 25 and 22·5 cycles per minute are too high, and the corresponding low results are due to injury from the jerks of the recording slide. At the speed 18·1, the frequency curve of the breaks (Fig. 3, Paper IV.) shows that this error is beginning to affect the results, and though they are not seriously wrong from the standpoint of routine testing, the mean for this speed is best omitted in evaluating the fine effect under discussion.

Within the limits of sound testing speed, the results of Table II. show an increase with speed but also considerable sampling differences. To obtain a general mean most free from instrumental and sampling errors, the sum of the differences was found between 1—3 and 6—7, and the ratio of the total change in F to the total change in log T gives a slope $-dF/d\log T =$ 24·2 from $\log T = \bar{1}\cdot97$ to $\bar{1}\cdot39$ through the point ($\log T = \bar{1}\cdot66$, $F = 447$ grams).

Shorter and Hall Autographic Load-Extension Instrument

The autographic instrument is reliable over a wide range of speeds if the time of vibration of the spring be kept small in comparison with the time of break. It was therefore used to obtain a direct comparison between the breaking loads at deadweight and Moscrop speeds on alternate threads and a measure of the change of final extension for a large difference in log T.

Tests were carried out on two sets of 48 alternate threads 64·5 cm. long. For the slow speed, the carriage was traversed by connecting it to the oil plunger of the deadweight tester adjusted to a fall of 3 inches per minute, each test occupying on the average 90 seconds. The other set was tested by traversing the carriage by hand at the highest speed consistent with steady movement, the break occupying about 0·4 second. An initial tension of 10 grams was applied to make the extension measurements more exactly comparable.

Table III.

	Fast Loading $T = 0\cdot4$ seconds.		Slow Loading $T = 90$ seconds.
Breaking load	418 ± 2·8	... ...	332 ± 2·4 grams.
Standard deviation	σ 28 = 6·7%	... ...	30 = 9·0%
Extension %	6·637 ± 0·043	... ...	6·645 ± 0·056
	σ 0·446 = 6·7%	... ...	0·556 = 8·4%
Load/extension	61·6 ± 0·3	... ...	48·4 ± 0·3 gms. for 1% extension.
	σ 3·0 = 4·9%	... ...	3·2 = 6·5%

$$\frac{-\Delta F}{\Delta \log T} = \frac{86}{2\cdot35} = 36\cdot6$$

The breaking load at the lower speed is in the same range as those obtained on the single thread tester, but at the high speed it is 29 grams lower than

the Moscrop result. While the latter may have been obtained on a stronger sample of yarn, it is nevertheless in accordance with other Moscrop tests made on the Sakel yarn, and the difference is probably or largely instrumental error.

In the extension measurements, the difference of 0·008% of the length is quite insignificant, and in view of the great difference in speed, may be taken as evidence that the final extension is independent of the speed of testing and is the determining factor of rupture. The extension found on the deadweight tester is not significantly different from that found on the autographic tester.

The shape of the load-extension curve allows a measure of the work of rupture, most conveniently obtained by the "work factor" (Paper II.). The initial tension of 10 grams takes out much of the very unresisting extension which produces the curve at the beginning of load-extension diagrams of yarn, without doing appreciable work, thus raising the work factor to little below 0·5. The figure cannot be measured with the same degree of accuracy as the final load and extension, and little error is introduced by taking the work of rupture as one half the product of breaking load and extension.

Ballistic Tester

Much quicker breaks can be made on the ballistic tester than on any machine depending on a static principle of measurement, but the result is in energy units. Assuming that the extension remains constant at 6·64%, the value given by the autographic tester, and that the work factor is 0·5, the breaking load—

$$F = \frac{100\, w}{3{\cdot}32} = 30{\cdot}1\ w \text{ grams.}$$

where w is the work of rupture in gram.cm. per cm. Possibly about 5% of the work of rupture is due to work done after the maximum load is attained (Paper II.), but the work factor may also be about 5% less than 0·5, the two errors affecting the calculation in opposite ways. The equivalent time of break for the ballistic test is calculated from Equation 37, Paper IV. As the rate of extension decreases during the break, this is not exactly comparable with the time taken in a test at constant rate of loading, and the resulting value of log T is rather an upper limit of approximation to the best value for the general relation.

Ballistic tests were done on cut-skein samples, the alternate threads of which were tested on the standard tester at the speed 3 inches per minute, with the results—

Ballistic Test—10 specimens of 30 threads, 16 inches long. Mean reading, 379 units, $w = 16{\cdot}41 \pm 0{\cdot}10$ grams.

$T = 0{\cdot}01$ sec. $F = 494$ grams.

Single Thread—283 specimens, 15·8 inches long.

$T = 76$ sec. $F = 353{\cdot}8 \pm 1{\cdot}1$ grams.

$$-\frac{\Delta F}{\Delta \log T} = 140/3{\cdot}68 = 38{\cdot}0 \text{ grams.}$$

Within the range of the ballistic tester, the speed may be varied in two ways, by breaking similar specimens with different heights of fall or by breaking different numbers of threads with the same fall.

Table IV.

Similar Specimens Broken by Bob Released from Varying Height. 54 Specimens of 30 Threads, 24 in. long, tested at each height

Release Machine Units	Reading Units	T seconds	w grams	F grams
500	192	·034	15·5	467
700	385	·024	15·8	477
900	592	·019	15·5	467
1100	780	·017	16·1	485

Table V.

Varying Number of Threads—Constant Height of Fall, 1,100 units. 20 Specimens of each size, 67·4 cm. long.

No. of threads	80	60	40	20	10
Reading—1st 10	173 ± 9·7	409 ± 7·8	624 ± 8·8	862 ± 2·3	975 ± 1·3
,, 2nd 10	187 ± 4·2	403 ± 6·5	638 ± 2·8	862 ± 2·3	977 ± 1·8
w grams	15·72	15·82	16·03	16·28	16·95
F grams	474	476	483	490	511
T sec.	·038	·026	·021	·018	·016

The figures show a definite trend upwards with speed, but the change is too small to be estimated accurately. For instance, the apparently large difference between the results on 10 and 80 threads is produced by nine units in the reading for the former test. The highest accuracy cannot be obtained when comparisons are made between different settings of the machine, as in Table IV., or when only a small fraction of the energy of the bob is absorbed. The most accurate difference is probably that between 80 and 40 threads in Table V., which gives a slope $-\Delta F/\Delta \log T = 34{\cdot}6$. The line of least squares drawn through the nine points in these tables fixes the slope as $-dF/d \log T = 62$, from $\log T = \bar{2}{\cdot}58$ to $\bar{2}{\cdot}20$ through the point ($\log T = \bar{2}{\cdot}35$, $F = 481$), but the quantitative accuracy of the slope is low.

Rupture Under a Constant Load

Numerous observations of breaking load under steadily increasing tension cannot be carried out conveniently at rates much lower than that at which one break takes 90 seconds on the deadweight tester. The decrease of breaking load for very much slower breaks can, however, be followed by the simple device of hanging weights from a set of threads which are left undisturbed till rupture, even though that may not occur for a month.

Sets of 250, 200, 175, and 150 grams were hung from threads of the 36s Sakel yarn in a humidified box (Paper I.) which maintained the conditions of 66% R.H. and 70° F. night and day, and the time was noted when each thread was found broken. Of 70 specimens loaded with 250 grams the first broke in 1 minute, the last in 23 hours; of 38 loaded with 175 grams, the first broke in 46 hours and 13 were still unbroken after 800 hours.

The apparently irregular and divergent range of duration of the individual threads does not appear at first sight to lead to any simple relation between rate of break and breaking load. The scatter, however, is purely a question of the method of expressing the time factor; for example, if this were expressed by the mean rate of extension, the later breaks would be crowded together instead of being widely scattered. The results can be made comparable with those of the standard test, independently of the method of expressing the time, by a simple assumption, namely, that if a set of threads

be tested under a slowly increasing tension or alternatively under a constant load which they can sustain for some time, the threads will break in approximately the same order. This need not hold strictly for each thread, but rather for frequency groups; in particular, the threads which would break at the middle of the range will be the same in each case. Thus in the results given in Table VI. half the threads have broken when the increasing tension attains 350 grams in the slow standard test, half have broken in 150 minutes under a constant load of 250 grams. Then, on the above assumption, if the breaking load of a thread be 350 grams when T is 80 seconds, it is 250 grams for a duration of 150 minutes under constant load.

There is this difference between the two methods, that in the first the average load during the whole time is half the breaking load, in the second the full breaking load. This does not affect the mutual comparison of results obtained by the latter method, but comparison with the former method is improved if the time of survival be doubled to give the value of T.

The transformation of the time distribution to strength distribution was made by using the strength frequency curve at the slowest speed on the single thread tester, at which 100 specimens had been tested before winding the yarn for the hanging weight test, and 283 specimens were tested after. The latter were used in a comparison with the ballistic test, giving close sampling between the extreme limits of speed.

For uniformity of expression, all the breaking loads (F in Table VI.) are given as those of the median threads by assuming that the loads for the different quartiles bear the same ratio to each other as in the slow standard test; for example, if the weakest thread breaks at 280 grams in the latter test and in one minute under 250 grams, then the median thread breaking at 350 grams will break in one minute under

$$\frac{350}{280} \times 250 = 312 \text{ grams.}$$

The plot of the results in Fig. 1 shows that the overlapping of the figures for the several loads is so consistent that this proportionality is justified.

Table VI.

Standard Tester No. of Tests 383			250 grams 70		200 grams 18		175 grams 38		150 grams 19	
Up to	% Broken		Time mins.	F	Time hrs.	F	Time hrs.	F	Time hrs.	F
280 gms.	2	1st break ...	1	312	4	250	46	218	120	187
330 ,,	25	1st quartile	33	265	36	212	200	186	800	159
350 ,,	50	Median ...	150	250	92	200	428	175	?	150
370 ,,	75	3rd quartile	350	236	202	189	800	166		
410 ,,	98	Last break	1400	213	610	171	?	149		

Within this very extended range there is still no definite sign of curvature and the best straight line through the points given by the medians and quartiles, weighted in proportion to the square root of the number of observations, is given by the slope $-dF/d \log T = 31{\cdot}2$ grams from $\log T = 3{\cdot}60$ to $6{\cdot}49$ through the point ($\log T = 5{\cdot}15$, $F = 220$).

A further test on 59 specimens under 250 grams was made on an independent sample, the results of which are shown by the dotted line in Fig. 1. It agrees with the first test as nearly as should be expected, allowing for sampling differences.

Beyond extending the relation to much greater durations, this constant load test gives a direct criterion for the method of expressing the time factor. The threads of a sample vary in such a way as to give an approximately normal or symmetrical distribution to most measurable characters.

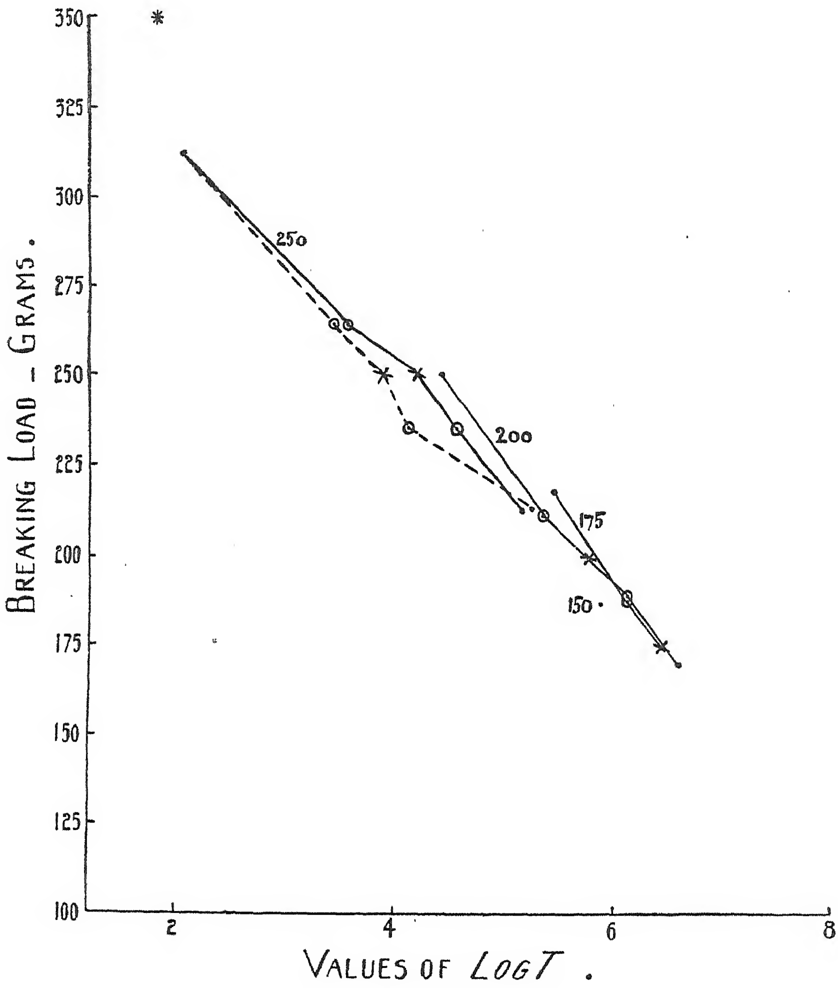

FIG. 1

Thus for breaking load, the mean, median, and most frequent values are nearly identical, the quartile deviation and maximum deviation nearly the same on either side of the median. When the load is kept constant and the strength is measured by the time of survival, the latter should be expressed by a function of which the mean value will also be approximately the median, at the middle of a symmetrical distribution.

There are several plausible methods of expression, the time T, $1/T$ which is proportional to the mean rate of extension and roughly to the rate of loading, and log T. The last has no *à priori* justification, but was found to give the simplest relation for the change of breaking load.

Table VII.
Values at Quartiles of T, $1/T$, and log T.

	Standard Test		Under 250 grams Load					
	F grams	Difference	T sec.	Difference	$1/T \times 10^5$	Difference	Log T	Difference
1st break ...	280		60		1667		1·78	
		50		1380		1616		1·52
1st quartile ...	330		1,980		51		3·30	
		20		7020		40		0·65
Median ...	350		9,000		11		3·95	
		20		12,000		6		0·37
3rd quartile	370		21,000		5		4·32	
		40		63,000		4		0·60
Last break ...	410		84,000		1		4·92	

From Table VII. it is plain that T and $1/T$ cannot be treated as quantities expressing strength, of which the mean value would represent a sample, but that log T might be used in such a way without very great error, though there is still a distinct skewness. The advantage of log T is also made clear by an examination of the results of the second test on 59 specimens, of which the mean value of the time T differs from the median by $+$ 1·62 times half the difference between the 1st and 3rd quartiles. For $1/T$ the ratio is $-$ 2·64, but for the function log T it is only $-$ 0·22. These ratios are roughly proportional to the skewness of the frequency distributions.

The Relation Between Breaking Load and Time

If the breaking load be expressed against the time from the beginning of loading to rupture, the curve is very concave to the abscissa, if against rate of loading it is very convex. It was found that the change could be expressed most simply against the logarithm of the time and the data obtained for a general relation between F and log T are collected in Table VIII. and shown graphically in Fig. 2.

Table VIII.
Collected Data on Relation between F and log T

Method	Range of log T	Mean Point F gm.	Mean Point log T	Slope $-\,dF/d$ log T
(1) Hanging weight ...	6·49 — 3·60 ...	220	5·15 ...	31·2

			Mean ...	37·1

Total Range of log T, 6·5 — $\bar{2}$·2, of F, 177 — 494 grms.

To a first approximation these results give a simple linear relation. The best straight line (judged) through the whole range is shown in Fig. 2 and it has a slope $-\,dF/d$ log $T = 37{\cdot}4 = 0{\cdot}10F_1$, where F_1 is the breaking load for a time of 10 seconds. From this line the absolute values deviate no more than might be expected from sampling differences. To the mean slope the local slopes approximate according to the accuracy of determination. That given by the standard tester differs only by the manner of

finding the general mean from the individual tests. The slopes obtained by methods 4 and 5 have little quantitative significance, and the individual values of which they are the mean include values very close to 37.

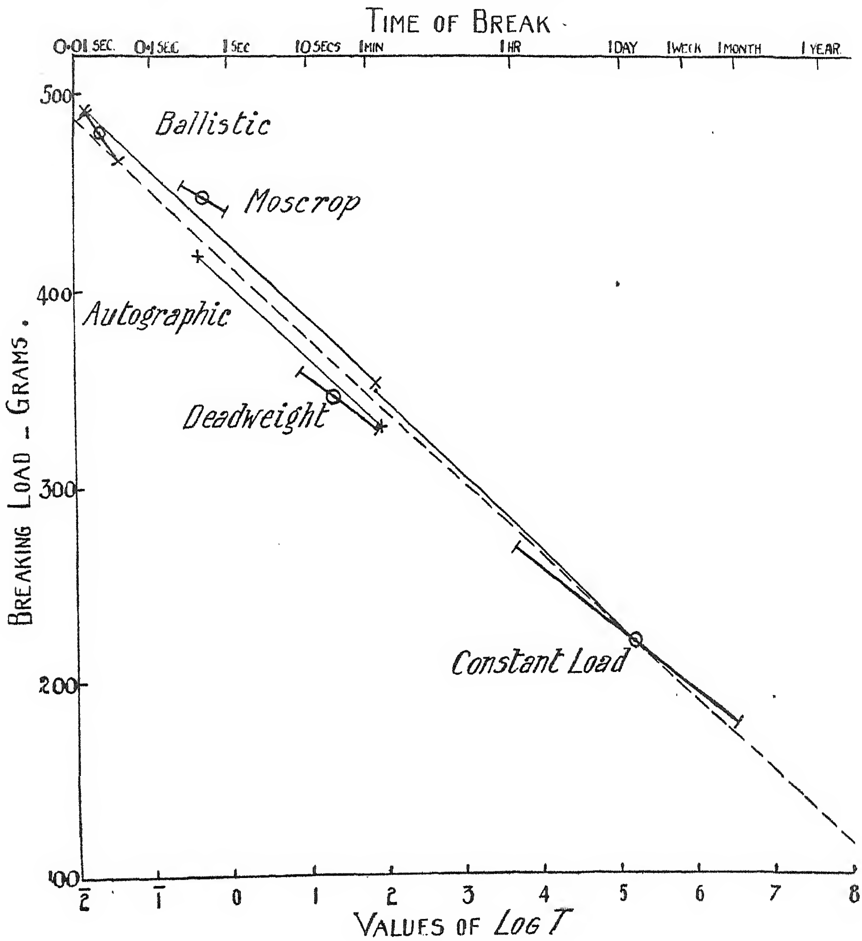

FIG. 2

In another paper[2] this logarithmic expression is related to other effects of elastic imperfection, and it is shown that limiting values must be reached at either end of the curve, but these do not seem to be approached within the limits of time covered by the present experiments. The slope from Method 1 is determined with considerable accuracy, and it may be really lower than the general slope. The fact that only one thread broke under a load of 150 grams in a month seems to point to a flattening out of the curve.

The logarithmic expression, however, covers the practicable range of experimentation with all the accuracy justified by the data or demanded for purposes of interpolation, &c., if not for theories on the physical cause.

The time effect has also been studied on the breaking load of single hairs of a Sakel cotton very similar to that which composes this yarn. It is surely significant that the identical formula $-dF/d\log T = 0{\cdot}1F_1$ applies

equally to the hairs and the yarn, in other words, that the ratio of yarn to hair breaking load remains constant, independent of the speed of testing.

The following measurements were made on the yarn and constituent hairs—

Yarn weight $= 1{\cdot}72 \times 10^{-4}$ gram per cm.
Hair weight $= 1{\cdot}39 \times 10^{-6}$ gram per cm.
$\therefore$ Average number of hairs per section $= 123{\cdot}4$.
Hair breaking load $= 5{\cdot}97$ gm. at a rate of loading $0{\cdot}5$ gm. per sec., i.e. $\log T = 1{\cdot}077$.
$\therefore$ Aggregate breaking load of hairs $= 737$ gm.
Yarn breaking load ($\log T = 1{\cdot}077$) $= 373$ gm. $= 0{\cdot}402 \times$ aggregate breaking load of hairs.

To interpret this ratio in terms of the properties of the hairs and yarn is a very complex question. It must be less than unity; first, because the hairs are oblique to the length of the yarn, so that the aggregate tension on the hairs is greater than that on the yarn; second, because the tensions and tensile properties of the hairs are not uniform (*vide* Paper V). These features of structure are not affected to any great extent by the rate of loading, and the effect of this will depend on the relative importance of fibre slip and rupture in determining the breaking load. It is possible that loosening of the least tightly held fibres proceeds during extension, throwing the load more and more on to the strongly gripped core till it ruptures. Examination of breaks under the microscope shows that rather more than half the hairs are snapped and no appreciable difference in type of break could be noticed between ends ruptured in the ballistic and hanging weight tests.

Comparisons have been made at the Manchester Chamber of Commerce Testing House[1] on the strength of fabrics as given by machines working at various speeds, and these also show a general increase of breaking load as the speed is increased. The most thorough is a test on cotton duck, alternate warp specimens being broken on an Avery and a Goodbrand machine. The first two sets, each with 500 tests on each machine, were carried out at the usual rates on specimens 2 in. wide. the times of break being 85 and 8 seconds respectively. For the third set, with 100 tests on each machine, the specimens were 1 in. wide and the rates adjusted to make the times of break equal, about 12 seconds. The results are given in Table IX.

Table IX.

	1st Set	2nd Set	3rd Set
Avery	426·5 ...	386·7 ...	252·1 lbs.
Goodbrand	454·3 ...	398·9 ...	237·5 ,,
Difference	−27·8 ...	−12·2 ...	+14·6 ,,

To make the relation between breaking load and time of break the same as for hairs and yarns, the difference in the first two sets due to speed should be about 40 lbs. Taking into consideration the difference shown by the machines working at the same rate, it appears to be of this order. Further, the extensibility did not differ appreciably in these tests.

31—IX.—TENSILE TESTS FOR COTTON YARNS
iv.—THE DYNAMICS OF SOME TESTING INSTRUMENTS

By Frederick Thomas Peirce, B.Sc., F.Inst.P.
(The British Cotton Industry Research Association)

INTRODUCTION AND SUMMARY

The operation of several testing instruments is analysed in order to detect possible errors due to momentum or friction, to find the degree of constancy attained in rate of loading and in sensitivity, to evaluate the time of break, and to show the possibilities of improvement in any of these respects. The treatment is mathematical throughout, practical applications being detailed in the earlier papers of this series.

Momentum errors do not attain serious proportions in the pendulum type of machine, especially when the lower jaw begins to move gradually as the specimen comes under tension—a condition realised in the single-thread tester operated by an oil plunger—and when the period of free swing of the pendulum is short. The effect of an eccentric roller on sensitivity, steadiness of movement and constancy of rate of loading is examined, and it is shown that an eccentricity one half the radius[1] greatly improves the efficiency of the instrument.

The variable velocity of the loading jaw of the Moscrop machine introduces slight momentum errors, which are not important at speeds which obviate more serious dangers, and a negligible variation of the rate of loading. An error is introduced by the fling of the pointer, which increases rapidly as the operation is accelerated but which can be measured. The jerk caused by starting the slide of the recording jaw into sudden movement may seriously affect the result and cannot be allowed for in a correction. The danger is avoided by slowing the machine down to 6 cycles per minute for strong yarns, or still more for very weak ones, using springs such that the specimens break in the second half of the record. Formulæ are given for the correction for fling and for a criterion of safe speed.

The load-extension instrument is free from error if the carriage be moved steadily and suitable dimensions of the spring chosen according to the analysis given by Shorter and Hall.[3]

Calculations are given for designing a ballistic tester to avoid impulsive reactions on the support and in the pendulum, for calibration in absolute units and for evaluating the rate and time of break.

PENDULUM TESTERS

The pendulum of a single-thread or lea tester of the standard type has an appreciable inertia and if its motion be not steady, the force on the yarn differs by the effective force of the acceleration from that given by static calibration.

In particular, if the lower grip be moving when the specimen comes under tension, the pendulum starts with a jerk, producing an oscillation which is imposed on the steady increase of load. Shorter[2] has evaluated

this error for the case where the lower grip is moving at full speed when the tension begins, and the specimen is perfectly elastic. This case is reproduced in practice if a fine copper wire be placed slackly between the jaws of a single-thread tester, and the oscillations are then very evident to eye and ear. With cotton yarn, however, such oscillations damp out very quickly, only three periods being detectable whether from the initial jerk or if restarted by momentarily checking the pendulum. The single-thread machine used in the present work is operated by a plunger in oil, which starts into movement as the tension begins, so that the initial jerk is quite negligible.

Shorter[1] also suggests an eccentric roller to obtain an even scale. As the very uneven scale of the concentric roller so restricts the range, the makers (Messrs. Goodbrand), at request, incorporated this modification in the single-thread tester used for this research. Incidentally a pendulum was thus obtained with a very short free period, 1·0 second, which further reduces the possibility of error from oscillations even with more elastic specimens. A vibration of a fraction of a second can be detected with sized yarns but dies out very early.

It is desirable that three quantities should be constant over the range of a tester, closeness of scale or sensitivity, momentum of the pendulum, and rate of loading. Constancy in all cannot be attained with the dead-weight principle, so it is necessary to inquire how close an approximation can be made, quite appreciable variations being allowable before the soundness of the test is impaired.

Let the radius of the roller be r, the axis be at a distance x from the centre, and the line joining them be horizontal when the tension is zero. If θ be the inclination of the pendulum from the zero position, the vertical movement of the upper grip (positive downwards) is given by—

$$y_2 = r(\theta + \lambda \sin \theta) \text{ where } \lambda = x/r. \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If the lower grip moves at a constant rate, its movement is given by—

$$y_1 = vt. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

As the lateral movement of the upper grip does not appreciably increase the distance between the two grips for a long specimen, the extension of the yarn is—

$$y_1 - y_2 = f/E \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where f is the tension on the yarn and E a constant when the load-extension curve is a straight line, which is usually nearly enough the case for yarn under steady loading.

The tension according to static calibration is—

$$f - I \cdot \frac{\delta^2 \theta}{\delta t^2} \cdot \frac{1}{r(1 + \lambda \cos \theta)} = Mgh \cdot \frac{\sin \theta}{r(1 + \lambda \cos \theta)} = R \frac{\sin \theta}{(1 + \lambda \cos \theta)} \quad (4)$$

where $R = Mgh/r$ is the maximum scale reading ($\theta = 90°$), M is the mass, I the moment of inertia, and h the distance from the axis to the centre of gravity of the pendulum. As oscillations damp out so quickly and the only cases of interest are where the movement is very nearly steady, no appreciable error is caused by neglecting the term in $\delta^2\theta/\delta t^2$ to obtain, from Equations 1, 2, 3, and 4—

$$vt = r(\theta + \lambda \sin \theta) + \frac{R}{E} \cdot \frac{\sin \theta}{1 + \lambda \cos \theta} \quad . \quad . \quad . \quad (5)$$

Then the three quantities which ideally should be constant are—

Closeness of scale, $\dfrac{\delta f}{\delta \theta} = R \cdot \dfrac{\lambda + \cos\theta}{(1 + \lambda\cos\theta)^2}$ . . . . (6)

Movement of pendulum, $\dfrac{\delta\theta}{\delta t} = \dfrac{v}{r(1 + \lambda\cos\theta)} \cdot \left[1 + \dfrac{R}{Er} \cdot \dfrac{\lambda + \cos\theta}{(1 + \lambda\cos\theta)^3}\right]^{-1}$ (7)

Rate of loading, $\dfrac{\delta f}{\delta t} = vR \cdot \dfrac{\lambda + \cos\theta}{r(1 + \lambda\cos\theta)^3} \cdot \left[1 + \dfrac{R}{Er} \cdot \dfrac{\lambda + \cos\theta}{(1 + \lambda\cos\theta)^3}\right]^{-1}$ (8)

The possible error due to effective force can be judged more directly from

$$I \cdot \frac{\delta^2\theta}{\delta t^2}$$

where I can be found from the period of free swing of the pendulum T, as

$$I = Mgh \cdot \frac{T^2}{4\pi^2} = Rr \cdot \frac{T^2}{4\pi^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(9a)}$$

and

$$\frac{\delta^2\theta}{\delta t^2} = \frac{v^2}{r^2} \cdot \frac{\lambda\sin\theta}{(1 + \lambda\cos\theta)^3} \cdot \left[1 + \frac{R}{Er} \cdot \frac{1/\lambda\sin\theta + \sin\theta \,.\, \cos\theta - 2\cos\theta - 2\lambda}{(1 + \lambda\cos\theta)^3}\right]$$
$$\times \left[1 + \frac{R}{Er} \cdot \frac{\lambda + \cos\theta}{(1 + \lambda\cos\theta)^3}\right]^{-3} \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(9)}$$

It may be seen from these equations that none of the three quantities is strictly constant for any value of λ. With a concentric roller, $\lambda = 0$, the scale opens out rapidly at higher angles, the rate of loading decreases, and the rate of movement increases slightly according to the extensibility of the specimen. If the scale is made even, the rate of loading and velocity of pendulum both increase with θ. The practical compromise is to allow the scale to open out slowly, keeping the rate of loading practically constant and to ensure that the accelerations do not introduce appreciable errors.

The three conditions are fully satisfied in practice by the round value $\lambda = 0{\cdot}50$, rather less than the optimum when evenness of scale alone is considered. In order to obtain numerical values from the above formulæ, the value of R/Er must be known. As the variations are not very sensitive to this value, it may be taken as 0·724, which is that for a yarn breaking at 325 gms. with an extension of 1 in. on a machine of range 470 gms., the pulley radius being 2 in.

On this point, it may be noticed that Equation 8 may be written—

$$\frac{\delta f}{\delta t} = \frac{vk}{1 + k/E}$$

where $$k = \frac{R}{r} \cdot \frac{\lambda + \cos\theta}{(1 + \lambda\cos\theta)^3}$$

is a constant of the machine. Comparison between machines is usually made by a quantity called "the machine rate of loading," which is the change of tension on an inextensible specimen for unit traverse of the loading jaw. This quantity is the constant k for, when $1/E$ is zero, $\delta f/v\delta t = k$.

On the other hand, for very extensible threads, the rate of loading tends to become independent of the machine and approach the value $\delta f/\delta t = vE$.

In practice, breaks usually occur when the lever is about the middle of the scale and the extensibility of single cotton yarn rarely varies outside 4—6%, so that the representative value taken for R/Er gives a much better approximation to actual conditions than the limiting values of zero and infinity, when the subject is the variation over the scale of any one machine.

The momentum error in the machine with eccentric roller was evaluated to be under 0·1 milligm. at 60° inclination, the free period being 1·0 second. The condition of steady motion may therefore be ignored. The variations of sensitivity and rate of loading are shown in Table I. and, when $\lambda = 0{\cdot}50$, are too small to be any disadvantage. With a concentric pulley, specimens should be tested on a machine of such range that the inclination does not exceed 60°.

Table I.

Ratio of Value of Quantities to that at Zero

Inclination, θ ...	60°	60°	90°	90°	0°
Eccentricity, λ	0	0·5	0	0·5	–
Scale divisions, $\delta\theta/\delta f$ ...	2·0	1·04	∞	1·33	1
Rate of loading, $\delta f/\delta t$ ...	0·63	1·11	0	1·09	1

In studying the effect of rate of loading on breaking load, the results are conveniently expressed against the time which would be occupied in breaking the specimen at the rate of loading which obtains at rupture, which is given by—

$$T = f/\frac{\delta f}{\delta t} = \frac{r}{v} \cdot \left[\frac{f}{R} \cdot \frac{(1 + \lambda \cos \theta)^3}{\lambda + \cos \theta} + \frac{e}{r}\right] \quad . \quad . \quad . \quad (10)$$

where the values of f, $\frac{\delta f}{\delta t}$, θ, and e are those at rupture.

For the particular machine used for the work of Paper III.—

$$T = \frac{120}{v} \cdot \left[\frac{f}{470} \cdot \frac{(1 + \frac{1}{2} \cos \theta)^3}{\frac{1}{2} + \cos \theta} + \frac{e}{5{\cdot}08}\right] \text{ seconds} \quad . \quad . \quad (10a)$$

The value of $\dfrac{(1 + \frac{1}{2} \cos \theta)^3}{\frac{1}{2} + \cos \theta}$

changes slowly and in the neighbourhood of 340 gms. is 1·94.

$$\therefore T = (0{\cdot}495\, f + 23{\cdot}6\, e)/v \text{ seconds} \quad . \quad . \quad . \quad . \quad (10b)$$

Before leaving the question of deadweight machines, the possible error due to overswinging should be considered. Suppose the pointer to continue to move after the specimen is ruptured, through an angle $\Delta\theta$, then neglecting friction—

$$\tfrac{1}{2}\, I\, \dot{\theta}^2 = Mgh - \Delta \cos \theta. \quad . \quad . \quad . \quad . \quad . \quad (Xa)$$

Substituting values given by Equations 6, 7, and 9a, and simplifying, the false increment to the breaking load is given by—

$$\Delta F = R\, \frac{v^2 T^2}{8\pi^2 r^2} \cdot \frac{\lambda + \cos \theta}{\sin \theta} \cdot \left[(1 + \lambda \cos \theta)^2 + \frac{R}{Er} \cdot \frac{\lambda + \cos \theta}{1 + \lambda \cos \theta}\right]^{-2} \quad (X)$$

For the particular instrument described above, the factors independent of θ reduce to 470/7896 gms. and the error, assuming

$$\frac{R}{Er} \text{ is } 0{\cdot}724,$$

is 0·015 gm. at 60°, 0·021 gm. at 30°. This is far below the limit of reading but with a smaller roller, longer pendulum, higher speed, and

less extensible material the error may become appreciable, and it is well to check this point by Equation (X) for any given instrument used in research testing.

MOSCROP MACHINE

The tension is measured by the extension of a spring working well within the limits of perfect elasticity, so the scale is accurately even. It is also sensitive enough for practical purposes.

As the inertia of the spring itself is very small and the extension too small to introduce elastic after-effects, the ratio of tension to extension is also independent of the speed. This may be experimentally verified over the large interval of speed between static calibration and free vibration. The period of free vibration is given by

$$T = 2\pi\sqrt{M/\mu}$$

where M is the load, μ the tension per unit extension during oscillation. Testing a spring of set No. 3 (maximum 16 oz.), steady calibration gave 0·316 cm. per oz. The time of vibration under an 8 oz. load was 0·32 sec., under a 13 oz. load 0·405 sec., giving 0·314 and 0·316 cm. per oz. respectively.

It follows also that the rate of loading would be constant if the loading jaw moved at constant speed and the tension on the yarn was equal to that on the spring. Any variations and errors must therefore be introduced by accelerations of the loading jaw and by the momentum and friction of the recording jaw.

The loading jaw is moved by a lever passing through a swivelled nut on the carriage. This lever is oscillated by a pin, on a uniformly rotating wheel, which passes freely up and down a slot in the lever. The geometrical conditions are shown in the diagram, Fig. 1; AQ, a fixed distance r, rotates at a constant angular velocity ω about A; OC moves so that it always passes through Q; P is the intersection of OC and the fixed horizontal line BP, and is a fixed point on the carriage. The length of BP, x, therefore defines the displacement of the loading jaw (positive to the right) from its position when the lever is vertical. Let x_0 be its value when the jaw closes at the beginning of loading, and let p be the number of complete cycles per minute. Then—

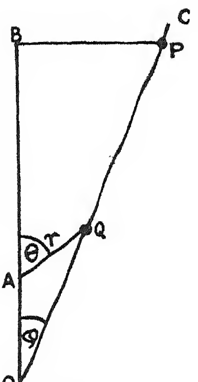

Fig. 1

$$x = \text{OB} \tan\varphi, \text{ where } \tan\varphi = \frac{\text{AQ} \sin\theta}{\text{AO} + \text{AQ}\cos\theta}$$

$$= b \cdot \frac{r \sin \omega t}{a + r\cos\omega t} \quad . \quad . \quad . \quad . \quad . \quad (11)$$

$$\dot{x} = \omega b r \cdot \frac{a\cos\omega t + r}{(a + r\cos\omega t)^2} \quad . \quad . \quad . \quad . \quad . \quad (12)$$

$$\ddot{x} = -\omega^2 b r \sin\omega t \cdot \frac{a^2 - r^2}{(a + r\cos\omega t)^3}$$

$$= -\omega^2 x \cdot \frac{a^2 - r^2}{(a + r\cos\theta)^2} \quad . \quad . \quad . \quad . \quad . \quad (13)$$

If y be the displacement of the recording slide from its zero position and the extension of the thread be $e = f/E$, where f is the tension in the thread—

$$x - x_0 = e + y \text{ and } f = E(x - x_0 - y). \quad . \quad . \quad . \quad . \quad . \quad (14)$$

As the spring is slightly extended at the zero position, let y_0 be the extension corresponding to the initial tension. The tension of the spring is

$$f' = \mu\,(y + y_0) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

The slide of the recording jaw is mounted on rollers with a very slight slope forwards, nicely adjusted so that the small forces due to friction and gravity neutralise each other in forward movement. Expressing the tensions in gravitational units, $f' = f - M\ddot{y}/g$, where M is the mass of the slide.

$$\therefore \mu\,(y + y_0) = E(x - x_0 - y) - M\ddot{y}/g$$

or $\quad M/g\,.\,\ddot{y} + (E + \mu)\,y = Ex - (\mu y_0 + Ex_0)$

$$= Ebr \cdot \frac{\sin\,\omega t}{a + r\,\cos\,\omega t} - (\mu y_0 + Ex_0) \quad . \quad . \quad . \quad (16)$$

Equation 16 is the differential equation of motion, with this reserve, that E is not a constant under oscillating tension. The initial jerk is rapidly damped out by elastic imperfection and the motion of the slide is thereafter steady except for the slow variation in speed of the loading jaw. Under conditions defined below, when the effective force of the slide is small in comparison with the tension, the term $M/g.\ddot{y}$ may beneg lected, giving—

$$y = \frac{E}{E + \mu} \cdot x - \frac{\mu y_0 + Ex_0}{E + \mu} = \frac{E}{E + \mu}\,(x - x_0) - \frac{\mu}{E + \mu} \cdot y_0 \qquad (17)$$

$$\dot{y} = \frac{E}{E + \mu} \cdot \dot{x} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

$$\ddot{y} = \frac{E}{E + \mu} \cdot \ddot{x} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (19)$$

The errors introduced by the momentum at the moment of rupture are—

(1) The difference between the tension of the yarn and of the spring due to acceleration of the slide which, denoting final tensions by the capital F, is—

$$F' - F = -\,M\ddot{y}/g \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (20)$$

and either (2) or (3), whichever be greater.

(2) The extension of the spring after rupture due to the momentum of the slide; the amount of this error, $\Delta' F$, is given by the energy equation—

$$\Delta' F/\mu \times F'\,.\,g = \tfrac{1}{2} M\,.\,\dot{y}^2$$

or

$$\Delta' F = \frac{\mu M}{2F'} \cdot \frac{\dot{y}^2}{g} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

(3) The fling of the recording pin, $\Delta F/\mu$, beyond the point where it is pushed by the slide. If m be its mass, ν the frictional coefficient—

$$\nu m g\,.\,\Delta F/\mu = \tfrac{1}{2} m\dot{y}^2$$

or

$$\Delta F = \frac{\mu}{2\nu g} \cdot \dot{y}^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

The ratio $\Delta F/\Delta' F = F'/\nu M$ is of the order 10, hence errors (1) and (3) only need be considered. The difference between the indicated strength, F_i, and the maximum tension in the yarn, F_m, is—

$$F_i - F_m = \frac{1}{g}\left(\frac{\mu}{2\nu} \cdot \dot{y}^2 - M\ddot{y}\right) \quad . \quad . \quad . \quad (23)$$

all the quantities referring to the moment of rupture. From Equations (18) and (19)—

$$F_i - F_m = \frac{1}{g} \cdot \frac{E}{E + \mu} \left(\frac{\mu}{2\nu} \cdot \dot{x}^2 - M\ddot{x} \right) \quad . \quad . \quad . \quad (23a)$$

All the quantities on the right of the equation are known except ν and E, which depends on the specimen.

Taking an actual case of a yarn breaking at 16 oz., extending 2·0 cms., tested at 8 cycles per minute against springs for a maximum strength of 32 oz.—M=4·17 oz.; ω=0·84 radian per second; E=8·0 oz. per cm.; μ=6·33 oz. per cm.; $E/(E + \mu)$ = 0·558; μy_0= 2 oz.; y = 2·21 cm.; $x - x_0$= 4·21 cm.; x = 14·41 cm. at break;

$$\text{Cos } \theta = (\sqrt{1 - 9{\cdot}7x^2/b^2} - 3{\cdot}27x^2/b^2) \,/\, (1 + x^2/b^2) = 0{\cdot}5369.$$

$$\dot{x} = 0{\cdot}10472\, p \times \frac{3{\cdot}27 \cos \theta + 1}{(3{\cdot}27 + \cos \theta)^2} \times 65{\cdot}5 = 10{\cdot}43 \text{ cm. per second.}$$

$$\ddot{x} = -\,\omega^2 x \cdot \frac{9{\cdot}7}{(3{\cdot}27 + \cos \theta)^2} = -\,6{\cdot}77 \text{ cm. per second.}$$

$$\text{The effective force error} = \frac{1}{g} \cdot \frac{E}{E + \mu} \cdot -\,M\ddot{x} = 0{\cdot}020 \text{ oz. on 16 ozs.}$$

This is equal to 1/100th of an interval on the record and is negligible.

The error due to the sliding of the pin is—

$$\frac{1}{g} \cdot \frac{E}{E + \mu} \cdot \frac{\mu}{2\nu} \cdot \dot{x}^2 = 0{\cdot}196/\nu \text{ oz.}$$

A slight upward inclination of the bed of the recording pin increases the effective value of ν, but, as the coefficient of friction between polished metal surfaces is of the order 0·2, this error may attain serious proportions in normal working.

As the research on rate of loading demanded enhanced speeds, the error had to be measured. This was done by placing a metal bar across the machine to stop the slides at a definite position near the breaking point of the yarn used in that research. The position of rupture being kept constant, the fling of the pin should be proportional to p^2. On Fig. 2 are shown the measured flings plotted against p^2. Below 5 cycles per minute, these are too small to be measured, but they increase rapidly in linear relation with p^2, the deviations being irregular and of the order of 0·2 mm., which cannot be regarded as significant. The fling was shorter and more regular when the pin was vaselined, being then 0·0064 p^2 mm. At the usual rate of 8 cycles per minute, this gives a fling of 0·4 mm.—rather more than 1/10th of an interval. It would be safer to make the standard rate 6 cycles per minute, 1 in 10 seconds, when the error is inappreciable.

The recording slide starts into motion with a jerk which may damage the yarn, for the moving jaw closes when travelling at 11·86 cm. per second (at 8 cycles per minute). This sets up an oscillation, but as it is very highly damped, the effective force in the first half period will show the likelihood of injury. Its magnitude may be found from Equation (16), simplified by taking the velocity of the loading jaw as constant at the value when the closes.

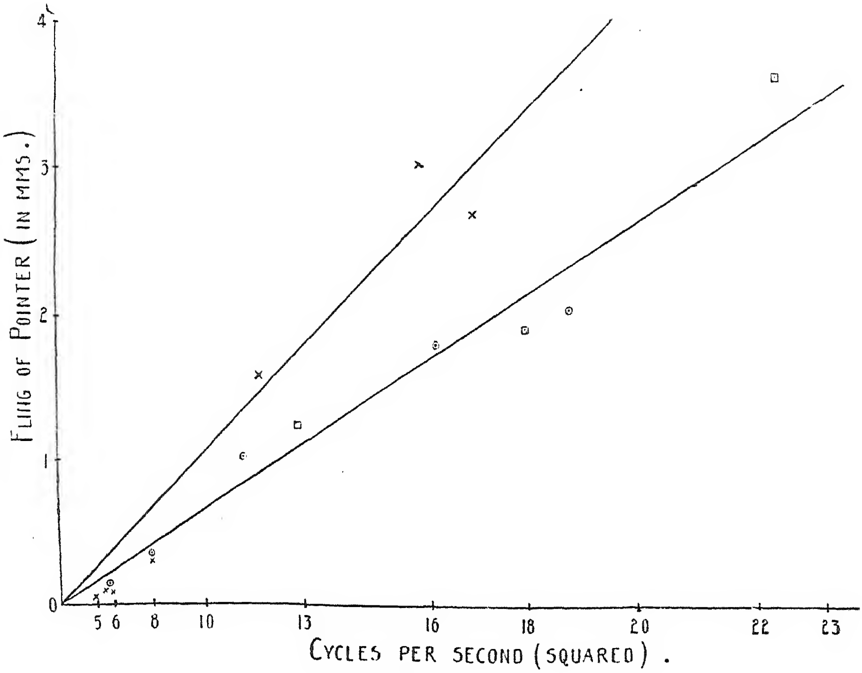

FIG. 2

Then $M/g \,.\, \ddot{y} + (E + \mu)y = E(x - x_0) - \mu y_0$

$$= E\dot{x}_0(t - t_0) - \mu y_0 \qquad \text{(16a)}$$

which may be written in the form—

$$(D^2 + a)y = bt' \qquad \text{(16b)}$$

where $a = \frac{g}{M}(E + \mu)$, $b = \frac{gE}{M} \cdot \dot{x}_0$, and $t' = t_0 + \frac{\mu y_0}{E\dot{x}_0}$, $dt' = dt$

The solution obtained by the general method is—

$$y = A \cos \sqrt{a} \,.\, t' + B \sin \sqrt{a} \,.\, t' + bt'/a$$

$$\text{and } \dot{y} = - A\sqrt{a} \sin \sqrt{a} \,.\, t' + B\sqrt{a} \,.\, \cos \sqrt{a} \,.\, t' + b/a$$

When the tension of the thread just equals the initial tension of the spring, $t' = 0$, $y = 0$, and $\dot{y} = 0$, whence $A = 0$ and

$$B = -\frac{b}{a\sqrt{a}} \cdot$$

Substituting, $y = \frac{b}{a}\left(t' - \frac{1}{\sqrt{a}} \cdot \sin \sqrt{a}\, t'\right)$

$$\dot{y} = \frac{b}{a}(1 - \cos \sqrt{a}\, t')$$

$$\ddot{y} = \frac{b}{\sqrt{a}} \cdot \sin \sqrt{a}\, t'$$

$$M/g\, \ddot{y} = E\dot{x}_0 \cdot \frac{1}{\sqrt{a}} \sin .\, 2\pi \cdot \frac{t'}{2\pi/\sqrt{a}} \cdot \qquad \text{(24)}$$

The oscillation of stress set up by the initial jerk has then an amplitude $E\dot{x}/\sqrt{a}$ and a period $2\pi/\sqrt{a}$. A similar oscillation is set up if the slide be held at rest under a slight tension of yarn and spring, and then disturbed. By trial the period is then a small fraction of a second as given by Equation (17), but the vibration is so highly damped that two periods can scarcely be detected. The amplitude under testing conditions is greatest when $t' = \pi/2\sqrt{a}$, succeeding oscillations being much less than given by the formula.

An extension of 5% and a break at the middle of the record give a value of E, $0{\cdot}3R$, which should be close to the value in most cases, while μ is always $0{\cdot}2R$ approximately, where R is the maximum reading of the record.

The amplitude of the initial jerk stress—

$$E\dot{x}_0/\sqrt{a} = 0{\cdot}0967\,\frac{E}{\sqrt{E+\mu}}\cdot p \qquad (25)$$

$$= 0{\cdot}1368\ E\ p/\sqrt{R}$$

$$= 0{\cdot}041\ p\sqrt{R}\ \text{oz. approx.}$$

The period of the oscillation—

$$2\pi/\sqrt{a} = 0{\cdot}41/\sqrt{E+\mu} \qquad (26)$$

$$= 0{\cdot}58/\sqrt{R}\ \text{sec. approx.}$$

The time from loading to rupture $(\theta - \theta_0)/\omega$

$$= (\theta - 0{\cdot}6816)/0{\cdot}1047\ p\ \text{sec.}$$

$$= 3{\cdot}08/p\ \text{sec. for a break at } \tfrac{1}{2}R.$$

For higher speeds and weaker springs therefore the initial jerk is more serious and the oscillations have less time to die down. As examples—
When $R = 4$ oz., $p = 8$ per minute,

then the amplitude $= \frac{2}{3}$ oz. on a 2 oz. breaking load.
the period $= 0{\cdot}29$ sec.,
and the time of break $= 0{\cdot}39$ sec.

Results under these conditions would be quite untrustworthy and the machine must be slowed down very considerably when using these weaker springs. As an arbitrary criterion it might be laid down that the period should not exceed one fourth of the time of break, nor the amplitude one fourth of the breaking load, the safe speed then being found from Equations 25 and 26—
When $R = 32$ oz., $p = 6$ per minute,

the amplitude $= 1{\cdot}85$ oz. on a 16 oz. breaking load.
the period $= 0{\cdot}10$ sec.,
and the time of break $= 0{\cdot}51$ sec.

Under these conditions results will be unaffected. The frequency curve of breaking loads in this case is shown in Fig. 3, Curve I., and the effect of increased speed is clearly shown in the Curves II. and III.

The rate of loading, ignoring momentum errors, is given by—

$$\delta f/\delta t = \mu\dot{y} = \frac{\mu E}{E+\mu}\cdot\dot{x} \qquad (27)$$

The velocity of the loading jaw, $\dot{x}$ (Equation 12), decreases during the loading from 11·9 cm. per second to 10·4 cm. per second at $R/2$, and 8·0 cm. per second at the top of the record, but this is not enough to affect the strength seriously. Using the same approximations as before, the rate of loading at rupture is 0·156 $p.R.$ oz. per second.

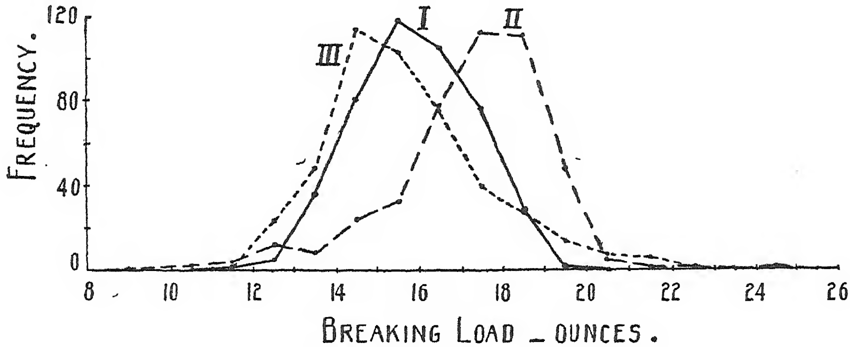

FIG. 3

Final extension 6·5%; 32 oz. spring; period of oscillation 0·11 sec.

I.—At 6 cycles per minute. Initial jerk 2·7 oz. Time of break 0·51 sec. Correction −0·15 oz. Normal frequency curve.

II.—At 18 cycles per minute. Initial jerk 3·7 oz. Time of break 0·17 sec. Correction −1·33 oz. Breaking load of most frequent group increased by greater speed but some 50 of the weaker threads affected by initial jerk.

III.—At 22·5 cycles per minute. Initial jerk 4·6 oz. Time of break 0·14 sec. Correction −2·06 oz. Most frequent group affected by initial jerk but many of the strong threads showing the normal increase of breaking load.

LOAD-EXTENSION INSTRUMENT

The equations of motion for the type of machine designed by Shorter and Hall[3] are very similar to those for the Moscrop tester, but there is more opportunity to vary the parts in order to eliminate errors. Oscillating stresses are overcome by making the period of the spring with recording jaw small in comparison with the time of break, the necessary calculations being given in the paper quoted. The driving mechanism can be arranged at will; the velocity of the moving grip can be made constant and the initial jerk avoided by using an oil-plunger drive.

The rate of loading is given by Equation 27, as for the Moscrop machine. When the carriage is moved steadily, the openness of scale, rate of loading, and momentum of recording system are all very nearly constant.

There is no friction to disturb the measurement, that of the recording needle on the glass plate being almost infinitesimal.

BALLISTIC TESTER

The essential point in the construction of a ballistic tester is to ensure that no appreciable energy is lost in the swing apart from that absorbed by the specimen. To this end, the anchorage, pendulum, and frame must be made rigid, that is, the distortion due to the breaking stress must be quite negligible compared with the extension of the specimen. The line of application of the stress must pass through the centre of percussion of the pendulum in order to avoid impulsive bending moments in the pendulum and reactions on the support.

The rigidity of the parts, friction of the bearings and pointer, dead stop of the latter, and uniformity of release are arranged for in the present instrument by mechanical details which were considered in Paper II. and which ensure freedom from the corresponding errors. Dynamical analysis is necessary to calculate the position of the centre of percussion, the energy and the rate of break.

If, as in the present case, the pendulum has two planes of symmetry intersecting in the longitudinal axis, its dynamics can be fully described by its mass, radius of gyration, and the position on the axis of the centres of suspension, of gravity, and of percussion. The grip for the specimen is made to coincide with the last point, preliminary calculations for the design of the pendulum having been made to ensure that its position would be convenient.

The mass M was found by weighing to be 3524·1 gms., the distance from the centre of suspension to the centre of gravity l was found by balancing on a knife edge to be 26·16 cm. The distance to the centre of percussion l_0 is obtained from the period of the pendulum—

$$t = 2\pi\sqrt{l_0/g} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (28)$$

The time of vibration was 1·24 secs., giving l_0 38·2 cm. Measurement from the centre of the axis to the centre of the rod on which the grip is placed gave 37·8 cm. in the finished machine. A rider was provided to adjust any such difference, but was not used as the disparity is sufficiently small. The radius of gyration, k, is given by the formula—

$$k^2 = l\,l_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (29)$$

as 31·6 cm. The moment of inertia $I = Mk^2 = 1{\cdot}114 \times 10^5$ gm. cm.^{2}

If θ_0 be the angular displacement of the pendulum at release, the height of the centre of gravity above its position at the bottom of the swing—

$$h_0 = l\,(1 - \cos\,\theta_0) \quad . \quad . \quad . \quad . \quad . \quad (30)$$

In falling this height, the kinetic energy acquired is $Mgh_0 = \frac{1}{2}Mk^2\omega_0{}^2$, and the angular velocity at the bottom of the swing—

$$\omega_0 = \sqrt{2gh}/k. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (31)$$

The energy gained in falling from the horizontal position—

$$\begin{aligned} Mgl &= 9{\cdot}05 \text{ joules.} \\ &= 92{\cdot}17 \times 10^3 \text{ gm. cm.} \\ &= 6{\cdot}67 \text{ feet-lbs.} \\ &= 80{\cdot}1 \text{ inch-lbs.} \end{aligned}$$

The scale is graduated in fractions of the total height of fall (equal intervals of $1 - \cos\,\theta$), and absolute values of the work are found by multiplying readings by the above values for the total capacity.

If a specimen be broken at the bottom of the swing, the centre of gravity rises to a height h_1 and the work of rupture—

$$\begin{aligned} W_1 &= Mg(h_0 - h_1) \\ &= Mgl\,(\cos\,\theta_1 - \cos\,\theta_0) \\ &= \int f\,.\,de \end{aligned}$$

where f is the force on the specimen at any moment, e its extension.

When the specimen is a lea of yarn in positive grips, the manner of break is given by the case analysed in Paper V. of gripped threads originally at the same tension. The complications involved in measuring the breaking load do not concern the measurement of work of rupture, but affect the precise rate at which the tension increases. Up till the rupture of the first thread, the tension increases proportionally with the extension, the ratio of load to extension ($E = f/e$) being the sum of the ratios for the individual threads. Thereafter the rate of increase diminishes to zero at the maximum load, the tension decreases, and suddenly ceases. The change of tension with extension during rupture is given by Equation (8c), *loc. cit.*, but not in a form suitable for calculation.

The rate of break and of loading for a specimen obeying Hooke's Law to rupture is more generally applicable and close enough to actual cases for practical purposes. The fixed grip of the tester is placed so that the specimen comes under tension just before the bottom of the swing and rupture is complete just after. During the extension, the pendulum grip is moving practically in a straight line with velocity $v = \omega l_0$, and

$$Mk^2 \frac{d\omega}{dt} = -f \, . \, l_0$$

$$\therefore f = Ee = -M \, . \, \frac{k^2}{l_0^2} \cdot \frac{dv}{dt}$$

$$\text{and } \frac{d^2e}{dt^2} = -\frac{l_0}{l} \cdot \frac{E}{M} \cdot e = -Ae \qquad (32)$$

Whence $$v = \frac{de}{dt} = \sqrt{C - Ae^2} = \left[\frac{2l_0}{Ml}\left(Mgh - \tfrac{1}{2}Ee\right)\right]^{\frac{1}{2}} \qquad (33)$$

where C is a constant of integration whose value is given by—

$$C = v^2 = 2gh_0 \cdot \frac{l_0^2}{k^2} = 2gh_0 \cdot \frac{l_0}{l} \, .$$

Integrating $t\sqrt{A} = \sin^{-1}\dfrac{e}{\sqrt{C/A}} + C_1$

When $t = 0$, $e = 0$, and $C_1 = 0$

$$\therefore t = \frac{1}{\sqrt{A}} \cdot \sin^{-1}\frac{e}{\sqrt{C/A}}$$

$$= \sqrt{\frac{l_0}{l} \cdot \frac{M}{E}} \cdot \sin^{-1} e\sqrt{\frac{E}{2Mgh_0}} \qquad (34)$$

The duration of the process of rupture is given by substituting the limiting extension for e. In the case of a lea, the mean breaking extension of single threads will give a sufficiently accurate measure of this slightly indeterminate time. It can also be expressed in the forms—

$$t = e\sqrt{\frac{Ml}{2Wl_0}} \cdot \sin^{-1}\sqrt{\frac{W}{W_0}} = \frac{0{\cdot}116e}{\sqrt{R - R_0}} \cdot \sin^{-1}\sqrt{\frac{R_0 - R}{R_0}} \text{ sec.} \qquad (34a)$$

the last applying to the particular machine, where R is the reading in 1/1000ths of the total capacity corresponding to the kinetic energy at the time t.

The rate of extension—

$$\frac{de}{dt} = \sqrt{\frac{2l_0}{Ml}} \cdot \sqrt{W_0 - W} = 8{\cdot}614\sqrt{R} \text{ . cm./sec.} \qquad (35)$$

and the tension at time t—

$$f = \frac{2}{e_1}\sqrt{W_1 W_0} \cdot \sin\sqrt{\frac{2l_0}{Ml}} \cdot \frac{\sqrt{W_1}}{e_1} \cdot t$$

$$= 184{\cdot}34\sqrt{R_0(R_0 - R_1)} \;/\; e_1 \,.\, \sin 8{\cdot}614\sqrt{R_0 - R_1}/e_1 \,.\, t \qquad (36)$$

where e_1 is the final extension.

The time which would be taken in stretching to rupture at the rate of extension obtaining just before rupture is—

$$T = e_1 \Big/ \frac{\delta e_1}{\delta t} = \frac{0{\cdot}116 e_1}{\sqrt{R_1}} \qquad (37)$$

32—X.—TENSILE TESTS FOR COTTON YARNS v.—"THE WEAKEST LINK" THEOREMS ON THE STRENGTH OF LONG AND OF COMPOSITE SPECIMENS

By Frederick Thomas Peirce, B.Sc., F.Inst.P.
(British Cotton Industry Research Association).

INTRODUCTION AND SUMMARY

It is a truism, of which the mathematical implications are of no little interest, that the strength of a chain is that of its weakest link. It is equally true that the strength of a test specimen is that of its weakest element of length, whether it be a metal rod, a thread of yarn, or a cotton hair. This fact distinguishes the quantity, breaking load, from most other quantities, such as weight of which the value is determined by the average over all elements of the length. Tensile strength thus decreases with the length of specimen in a way which is definitely calculated from the distribution of strength of short specimens. The decrease in mean strength and in irregularity is directly proportional to the irregularity of the short specimens and to a factor, depending only on the multiple by which the length is increased and very simply calculated therefrom.

Variability along a specimen is shown necessarily to introduce negative skewness into all frequency curves of strength, counteracting or reinforcing any skewness that may arise from methods of production, and this must be taken into consideration when drawing conclusions from the shape of strength frequency curves. In cotton yarns, the method of production tends to produce positive skewness which is found with specimens of 3 inches. This is obliterated to yield a symmetrical curve by increasing the length to a foot or so, while leas show decided negative skewness. More generally, skewness is produced by irregularity in the frequency curves of any quantity "when the deviations of individual values are affected unequally by equal deviations of opposite sign among the constituent elements of a specimen," a criterion which fits most elastic measurements.

The relations between the strength of fibres, yarns, leas, and fabrics have often been studied empirically, but they are subject to so many disturbing factors that measurements do not lead to definite or simple conclusions, in the absence of a logical basis for comparing the results. In the present paper, five cases of specimens composed of parallel elements are analysed for a relation between the strength of the whole and of the parts. Actual specimens of all kinds of materials may reproduce the conditions more or less closely. The lea test can be brought under a simple case if modified as suggested in Paper I. of this series.

A correction is given for measurements of tendering when only a fraction of the length of a specimen is subjected to treatment, such as wear or exposure to light.

The present paper is mathematical throughout, but the conclusions are condensed into simple forms applicable to experimental results in this series or elsewhere.

VARIATION OF STRENGTH WITH LENGTH

Let the distribution of the breaking loads of specimens of length l be expressed by a frequency curve, $y_1 = \varphi(f)$, where $y_1 \delta f$ is the probability that the strength of any given specimen should lie between f and $f + \delta f$, and further suppose that this function does not vary significantly from one portion to another of the whole batch of specimens.

The probability that the strength of any one thread should not be less than f is

$$\int_f^\infty \varphi(f)\,.\,df$$

that one of r lengths has a strength lying between f and $f + \delta f$ is $r\varphi(f)\,.\,df$; that none of the others has a strength less than f is

$$\left[\int_f^\infty \varphi(f)\,.\,df\right]^{r-1}$$

Hence the probability that the breaking load of any given specimen of length rl lies between f and $f + \delta f$ is $y_r\,.\,\delta f$, where

$$y_r = r\varphi(f)\left[\int_f^\infty \varphi(f)\,.\,df\right]^{r-1} \qquad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

This is a general expression independent of the form of the frequency curve provided only this be not also a function of the position of the specimen. It may be applied to any empirical frequency curve to deduce the distribution of strength in specimens of multiple lengths by giving each observation the weight $r\,(N'/N)^{r-1}$ where N' is the number of specimens of equal or greater strength, N the total number, or by the expression—

$$y_r = r\,\Sigma\,(N'/N)^{r-1} \qquad . \quad . \quad . \quad . \quad . \quad . \quad (1a)$$

the summation extending over the y_1 specimens in the interval.

Taking as an example the measurements on 10 in. and 30 in. lengths of 32's American ring yarn, of which the results are given in Table I. of Paper I., the distribution for the 30 in. lengths deduced from that for the 10 in. lengths are compared with the observed distribution in Table I. below (last two rows).

Table I.

Comparison of Breaking Loads of 10 and 30 in. specimens—32's American Ring Yarn

Interval	130 to	140	150	160	170	180	190	200 gm.
y_1	0	0	3	10	20	18	29	24
N'	200	200	−198	−188	−168	−150	−121	−97
$3\Sigma(N'/N)^2$ ...	—	—	9	28	46	34	39	21
y_3	2	0	3	12	27	38	33	29
Interval	210 to	220	230	240	250	260	270	280 gm.
y_1	23	36	17	8	8	3	0	1
N'	−74	−38	−21	−13	12−5	4−2	1	1
$3\Sigma(N'/N)^2$ ...	13	9	1	0	0	0	0	0
y_3	24	14	10	7	1	0	0	0

The derived and observed distributions agree well enough, considering the small number of observations for the operation of the law of probability, but show a discrepancy due to a general property of yarn. The actual loss

in strength and decrease in spread are less than those calculated because the average deviation between consecutive specimens is less than that between specimens widely separated or chosen at random, i.e. $\varphi(f)$ fluctuates along the length to a slight extent.

The frequency curves from the tests on 600 specimens of 9 in. and 27 in. lengths are shown in Fig. 1. The observed curve for the longer length (II)

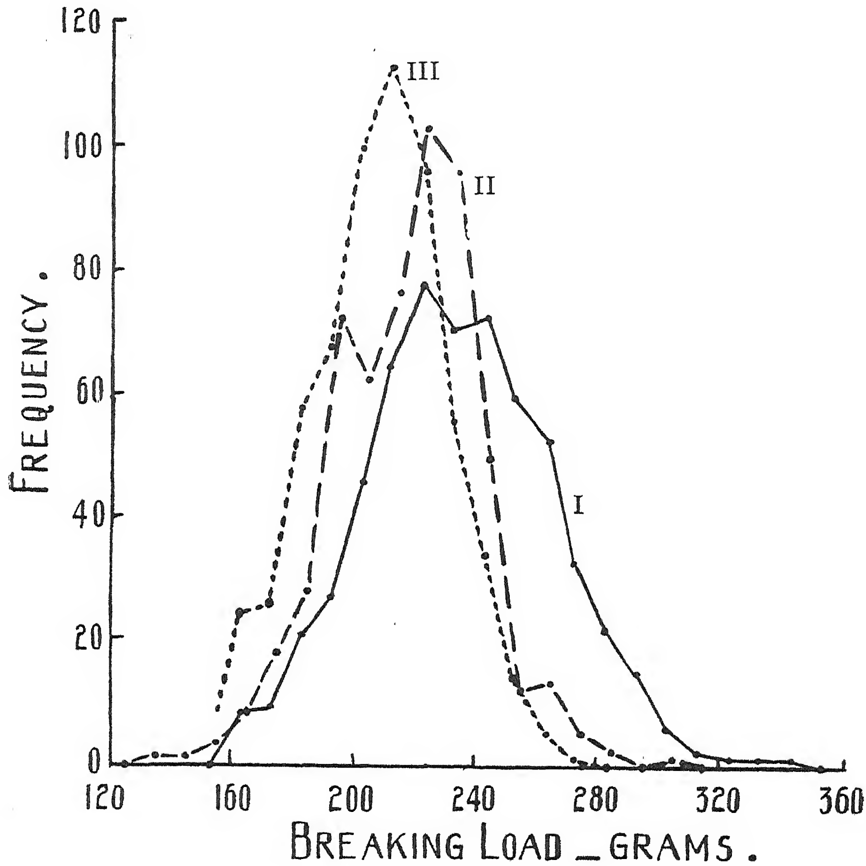

FIG. 1

shows a marked decrease in mean strength and in standard deviation, but the change is less than that given by the transformation (III) of the curve for the short specimens (I).

To obtain an analytical expression for the variation with length, it is necessary to assume one for the original frequency curve. Though observed frequency arrays are commonly irregular and may be skew, the normal curve is the most convenient general form and gives a sufficiently close approximation for the present purpose. The distribution of strength for a multiple length is then given by writing in Equation (1)—

$$\varphi(f) = \frac{h}{\sqrt{\pi}} e^{-h^2 (f-a)^2} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where a is the mean and h the "modulus of precision" for lengths l, the latter being equal to $1/\sqrt{2}\sigma$ (σ being the Standard Deviation). Then, writing $f - a = x$

$$y_r = r \cdot \frac{h}{\sqrt{\pi}} \cdot e^{-h^2x^2} \left[\frac{1}{\sqrt{\pi}}\int_0^\infty e^{-h^2x^2} \cdot hdx - \frac{1}{\sqrt{\pi}}\int_0^x e^{-h^2x^2} \cdot hdx\right]^{r-1}$$

$$= \frac{h}{\sqrt{\pi}} \cdot e^{-h^2x^2} \cdot r \left[\frac{1 - \Phi(hx)}{2}\right]^{r-1}, \text{ where } \Phi(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2} \cdot dx \qquad (1b)$$

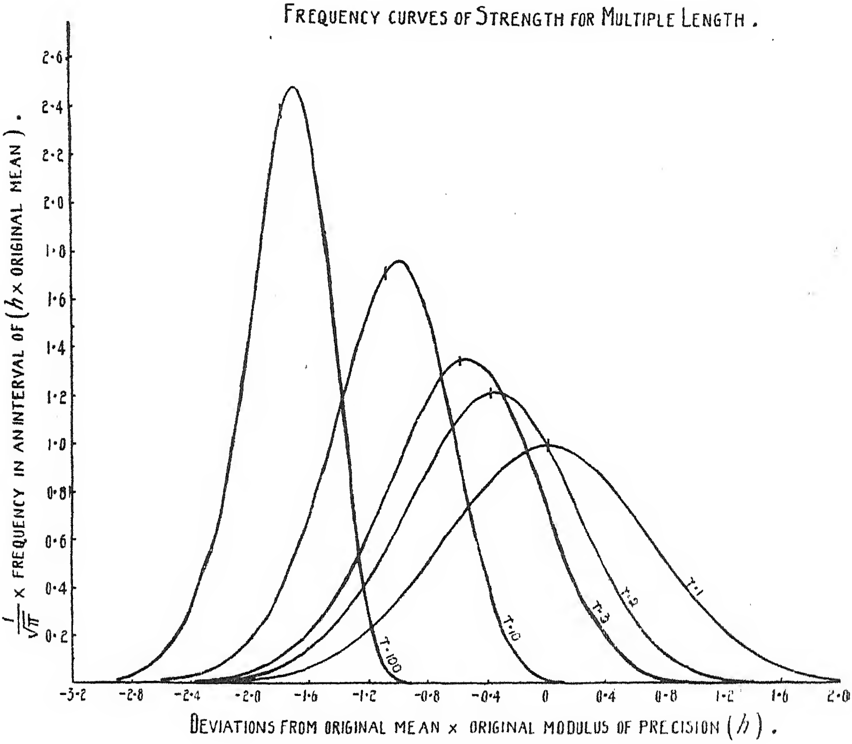

FIG. 2

The error function, $\Phi(x)$, cannot be obtained in the form of an integrated algebraic expression, and in consequence no such form can be obtained for the frequency function, y_r, the mean or standard deviation of the breaking loads of specimens of length rl. The error function can, however, be integrated by series and tables of its values are published. From these, curves have been drawn (Fig. 2) showing a normal frequency curve for a length l and the derived curves for lengths $2l$, $3l$, $10l$, and $100l$. For simple and general application, these have been plotted against multiples of hx for abscissa and $1\sqrt{\pi}$ for ordinate.

It will be seen that the mean strength decreases continuously with length, and the height of the peaks show that the standard deviation also

decreases. In addition the curves become negatively skew so that the mean, median, and mode are no longer identical. Of these, the last two can be obtained without integrating y_r.

The mode is given by the condition—

$$\frac{d}{df} \cdot y_r = 0$$

or

$$\varphi(f) \cdot \left[\int_f^{\infty} \varphi(f) \, . \, df\right]^{r-2} \cdot \left\{(r-1)\,\varphi(f) + 2h^2(f-a)\int_f^{\infty} \varphi(f) \, . \, df\right\} = 0$$

The first two factors are zero when $f = \pm\infty$, the mode being given by the condition that the expression in curly brackets be zero, or—

$$\frac{h^2(a-f)}{\varphi(f)} \cdot \int_f^{\infty} \varphi(f) \, . \, df = \frac{r-1}{2}$$

or

$$\frac{hx}{e^{-h^2x^2}}\left[\frac{1-\Phi\,(hx)}{2}\right] = -\frac{r-1}{2\sqrt{\pi}} \qquad . \quad . \quad . \quad (2a)$$

The median is given by the condition that one half the specimens contain a length l of strength less than the median, i.e. the probability that 1 in r lengths has a strength less than the median is $\frac{1}{2}$. The probability that any one length deviates below the mean by more than hx is

$$\frac{1-\Phi\,(hx)}{2}$$

that one or more of r lengths shows such a deviation is

$$1-\left[1-\frac{1-\Phi\,(hx)}{2}\right]^r = 1-\left[\frac{1+\Phi\,(hx)}{2}\right]^r$$

which probability is $\frac{1}{2}$ for strengths below the median of lengths rl. Hence, if hx be the deviation from the original mean of this median,

$$\left[\frac{1-\Phi\,(hx)}{2}\right]^r = \frac{1}{2} \qquad . \quad . \quad . \quad . \quad . \quad (3)$$

or

$$\frac{1-\Phi\,(hx)}{2} = 2^{-\frac{1}{r}}$$

The mean strength of the multiple lengths, a_r, is given by

$$a_r = \int_{-\infty}^{+\infty} y_r . f \, . \, df \qquad . \quad . \quad . \quad . \quad (4)$$

which can in general only be evaluated by calculations from plotted curves.

It is a simple matter to plot the functions of (hx) on the left hand side of Equations (2a) and (3), and read off the values which satisfy these equations for any value of r. A number of such values are shown in Table II. and the curves for the decrease in median and mode are given in Fig. 3. It is generally approximately true of a skew curve that the difference between the mean and mode is three times that between mean and median. The values of the mean obtained on this assumption are also shown.

Table II.*
The Strength of Multiple Lengths

r	Mode	Median	Mean	S.D.$\times\sqrt{2}$	—Sk.	$r^{-\frac{1}{5}}$	$3(1-r^{-\frac{1}{5}})$
1	0	0	0	1	0	1	0
2	·360	·386	·399	·82	·067	·87	·388

1000	2·202	2·266	2·30	·35	·388	·25	2·25

*The Skewness, $Sk = \dfrac{\text{Mean-Mode}}{\text{S.D.}}$. The other quantities are given as the deviation below the original mean multiplied by the modulus of precision h of the normal curve for $r = 1$. As mean and mode are found from plotted curves, the last figure is uncertain. To express these values as ratios of the S.D. of the original curve, multiply by $\sqrt{2}$.

The value for S.D. $\times \sqrt{2}$ is the inverse of the height of the curve, in Fig. 1, at the mean.

The last two columns give a general approximate formula for S.D. and mean.

As the difference between mode and median rapidly approaches a constant value 0·065, the skewness for large multiples is given approximately by $-0{\cdot}138\ r^{-\frac{1}{5}}$.

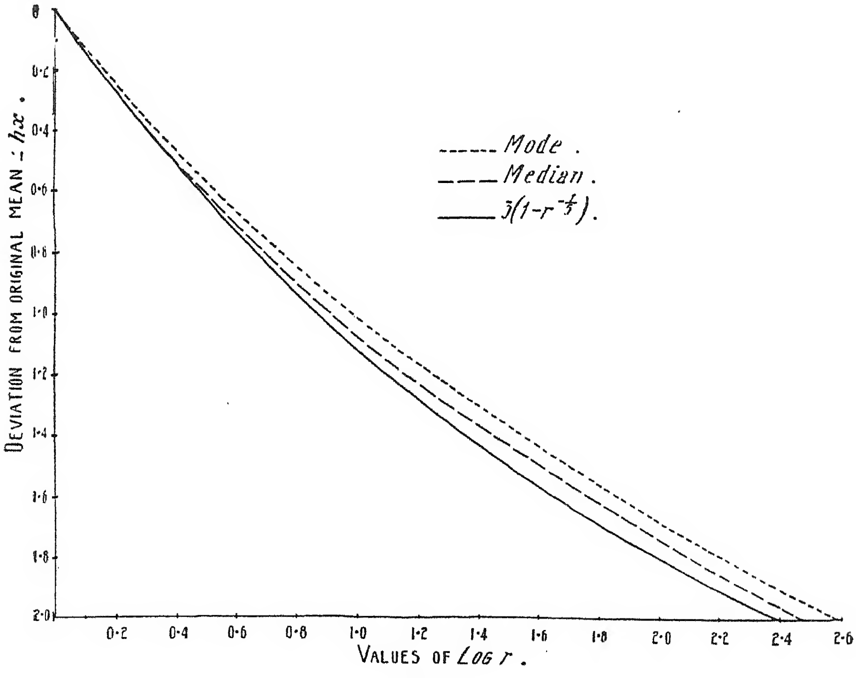

Fig. 3

*Since this was written, a paper[4] has been published with a very detailed table of the range between the extreme individuals of samples taken from a normal population. From Table X., *loc. cit.*,[4] the values given in this table can easily be calculated to six significant figures. The tables agree closely though obtained independently by very different methods. Table I.[4] also shows that the approximation to the S.D. is very satisfactory.

If the curves remained normal, the standard deviation would be inversely proportional to the height of the curve. Owing to the introduction of skewness the spread is somewhat greater, and it is better and sufficiently accurate to take the ordinate at the mean as the measure of S.D. The skewness is then given by—

$$\mathrm{Sk} = \frac{3}{\sqrt{2}} \cdot \frac{\text{median} - \text{mode}}{y_r \text{ at mean}}$$

the median and mode being given by deviations below the original mean in terms of $1/h$.

From the curves $r = 10$ and $r = 100$, the mean and S.D. were calculated from the ordinates at intervals $hx = 0{\cdot}05$, as from an experimental curve, giving values, expressed as in Table II., for the mean 1·087 and 1·769, for $\sqrt{2} \times$ S.D. 0·605 and 0·441, and for skewness $-$ 0·189 and $-$ 0·288, respectively.

The mean for the curve $r = 2$, may be obtained by an independent argument, assuming normal distributions. Suppose a length $2nl$ be tested in $2n$ lengths of l, and alternatively in n lengths of $2l$. Let f be the strength of the weaker of a pair of lengths l, f' of the stronger.

$$\text{The mean of the } 2n \text{ lengths} = \frac{\Sigma f + \Sigma f'}{2n},$$

$$\text{of the } n \text{ double lengths} = \frac{\Sigma f}{n} = \frac{2\Sigma f}{2n}.$$

$$\text{The difference of the means} = \frac{\Sigma(f' - f)}{2n}$$

$$\text{In a normal distribution } \sqrt{\frac{\Sigma(f' - f)^2}{n}} = \sqrt{2} \,.\, \sigma$$

where σ is the S.D. for the single lengths, and f and f' are any two values taken at random, also the mean absolute difference is $\sqrt{2/\pi}$ times the root mean square difference, or

$$\frac{\Sigma\,(f' - f)}{n} = \frac{2\sigma}{\sqrt{\pi}}$$

$$\therefore \text{ The decrease in mean strength} = \frac{\sigma}{\sqrt{\pi}} = 0{\cdot}565\,\sigma = 0{\cdot}399/h.$$

The above values for the mean when $r = 2$, 10, and 100, agree within a fraction of 1% with those calculated from the mode and median, which may be accepted for all the values of r. The argument for double lengths shows most simply the fact that the loss in strength is determined by the differences within the multiple length, the "internal" variability of long specimens, and that the changes in strength and regularity will be less than those calculated from the variability of a large batch of short specimens, when, as in cotton yarn, consecutive lengths tend to be more similar.

In practice it is most convenient to express the changes in terms of the mean and standard deviation. If a_l be the mean from lengths l, σ_l the standard deviation, then—

$$a_l - a_{rl} = v_r \,.\, \sigma_l \qquad (5)$$

$$\text{and} \quad \sigma_{rl}/\sigma_l = u_r \qquad (6)$$

where v_r and u_r are independent of the variability and are known functions of the multiple r, if the curve for lengths l be normal. It is not practicable, from the irregular frequency curves actually found from yarn, to determine whether the shorter length gives a normal curve nor to allow for skewness if present. To obtain a general expression for the effect of length on strength, small changes in v_r and u_r due to skewness must be ignored and simple relations between them then appear. For, from (5) and (6)

$$a_l - a_{rsl} = v_{rs} \, . \, \sigma_l \qquad (5a)$$

and $$\sigma_{rsl}/\sigma_l = u_{rs} \qquad (6a)$$

Also $$a_{rl} - a_{rsl} = v_s \, . \, \sigma_{rl} \qquad (5b)$$

and $$\sigma_{rsl}/\sigma_{rl} = u_s \qquad (6b)$$

$$\therefore \quad a_{rl} - a_{rsl} = (v_{rs} - v_r) \, \sigma_l$$

and $$\sigma_{rsl}/\sigma_{rl} = u_{rs}/u_r$$

Whence $$v_s \sigma_{rl} = (v_{rs} - v_r)\sigma_l \quad \text{and} \quad \frac{\sigma_{rsl}}{\sigma_{rl}} = \frac{u_{rs}}{u_r}$$

or $$v_s = \frac{v_{rs} - v_r}{u_r}$$

and $$v_{rs} = v_r + v_s \, . \, u_r = v_s + v_r \, . \, u_s$$

$$\therefore \quad \frac{v_r}{1 - u_r} = \frac{v_s}{1 - u_s} = \text{constant} = c$$

or $$v_r = c \, (1 - u) \qquad (7)$$

But $u_{rs} = u_r \, . \, u_s$, whence by continuing to factorise r and s comes the relation that u for any value of r is equal to the product of u for the factors of r, or to the nth power of u for the nth root of r.

$$\therefore \quad u_r = u_e^{\log_e r} = r^b \text{ where } b = \log_e u_e \qquad (8)$$

and $$v_r = c(1 - r^b); \quad u_r = r^b \qquad (9)$$

The values of c and b from the values given in Table II. change slowly with r concurrently with the increase of skewness, but a sufficiently good approximation is given by the values 3 and $-\frac{1}{5}$ respectively, when the change of mean is expressed in units $1/h$, or 4·2 and $-\frac{1}{5}$ in Equations (5) and (6), and 5·3 and $-\frac{1}{5}$ when calculating the effect from the mean deviation of the shorter lengths. The values given by this general formula, *vide* Table II., are as close as the assumption of normal distribution for an empirical frequency array warrants.

SKEWNESS

It has been shown that if the strength of specimens of any given length varies according to the normal law, then the frequency curve for longer specimens is negatively skew or, in general, strength distributions cannot be expressed by a normal or symmetrical frequency curve. The argument remains unaltered for any quantity of which the value for a specimen is determined by the minimum value occurring among its elements. By simply subtracting each value from a large fixed value, it is seen that positive skewness is necessarily introduced into the distribution of any quantity determined by a maximum value among the elements of the specimen, e.g., the thickness of cloth measured between plates without compression. To a less degree, but sufficient to make the normal law theoretically inapplicable, skew distributions will be found whenever the deviations of individual values are affected unequally by equal deviations of opposite sign among the constituent elements of a specimen, e.g. the torsional rigidity of rods or the bending moments in bars.

This class of quantity is so large and important that it is highly desirable to reproduce (1b) with an algebraic type of curve. As it is derived from the normal curve, the type to suggest itself is

$$y = e^{-h^2x^2} \ (a + bx + cx^2 + \ . \ . \ .). \qquad (10)$$

Some attempts were made to obtain analytical expressions for the constants of such a formula by fitting it at the median, mode, and original mean, but even with one or two terms only, the result is a complicated implicit function for the decrease of mean. The curve for long specimens, say $r = 100$, is closely imitated by

$$y = y_0 x^{-p} \, . \, e^{-r/x} \qquad (11)$$

Elderton[2] gives this curve fitted to mortality-age figures and it is not unreasonable to connect up such statistics with the above analysis by supposing death to result from the failure of the weakest of a number of bodily functions, the potential life of each varying in a normal manner. There does not seem, unfortunately, to be any algebraic expression for curves of type (1b) comparable in simplicity with the normal law.

The skewness, like the drop in strength, depends on the "internal" variability. If this be small compared with the variations between individuals due to their different origin, the skewness will be negligible or determined by the nature of the production. The distribution of strength of cotton hairs from a commercial sample does not show systematic skewness, being governed by the large differences between individuals due to differences in growth, these fitting into the criterion for normal distribution, that "the deviations be constituted by the summation of a very large number of independent deviations."[5]

In the case of cotton yarns, the element of length is that which is just too great to be spanned by a cotton hair. For specimens a few inches in length, the strength distribution should be unaffected by the skewness due to "internal variability" and be governed by the nature of production. This does not obey the normal criterion as the number of hairs per section gives a positively skew array, owing to the tendency of bunches of hairs to remain together in drafting. Moreover, twist runs into thin more than thick places, so that the strength increases with fibre number to a power lower than unity, which also tends to introduce positive skewness.[3] Very short specimens should therefore give more or less positively skew distributions. Andrews and Oxley[1] have found the skewnesses $+ 0{\cdot}085$ and $+ 0{\cdot}173$ from two sets of 5,000 observations on 3 in. lengths. With longer specimens this skewness should decrease to zero and become negative. Specimens of 12 in., tested by pendulum and Moscrop testers, show no systematic skewness which agrees with theory, the skewness for $r = 4$ being $- 0{\cdot}128$.

LOCAL TENDERING

In tests of tendering by wear and by light, a portion of each specimen is often exposed, the remainder being unaltered. The effect cannot then be strictly estimated by comparing the strength of untreated and treated specimens as the original strength of the tendered portions would be that of the partial, not the whole, length.

Let the total length of specimen be rl, the length tendered l, $\varphi(f)$ the frequency function of strength for untendered lengths l, $\varphi'(f)$ of tendered

lengths. The strength distribution of untendered lengths rl is as before given by Equation 1. For lengths rl, of which a portion l has been tendered,

$$y'_r = \varphi'(f)\left[\int_f^\infty \varphi(f)\,.\,df\right]^{r-1} + (r-1)\,\varphi(f)\left[\int_f^\infty \varphi(f)\,.\,df\right]^{r-2}\int_f^\infty \varphi'(f)\,.\,df \qquad (12)$$

This is a rigorous and general expression which may be greatly simplified for practical purposes if the tendering is large enough to localise the breakages. In this case the apparent tendering is $(a_r - a_1')$ and the real tendering—

$$\begin{aligned}(a_1 - a_1') &= (a_r - a_1') + (a_1 - a_r)\\ &= (a_r - a_1') + v\sigma_1\\ &= (a_r - a_1') + \frac{v}{u}\cdot\sigma_r \qquad (13)\end{aligned}$$

As the effective value of σ in yarn may be rather less than that calculated in the usual way over a large batch, the value of r should be kept as small as possible to minimise the correction. A practical and simple correction of $(+\, v\sigma_r)$ would be in accord with the theory and with the experimental results shown in Table I., Paper I.

COMPOSITE SPECIMENS

Actual specimens are never mathematical units of homogeneous properties, but may be regarded as built up of elements both of length and cross-section. The relation between the strength of elements of length and of long specimens has been derived; that between elements of cross-section and the composite specimen is of a more complicated nature. The problem is involved in the strength of leas of yarn, of a yarn in terms of fibre strength, of a fabric in terms of yarn strength, of electric wire flex, of silk threads, and even of a wooden or metal bar if the cross-section be regarded as constituted of parallel elements.

The relation between the strength of the elements and of the composite specimen depends on the variations of tension and of limiting extension among the strands. Actual conditions may be approximated to by one of several mathematically definite cases.

Case (*a*)—Strands gripped at the ends, of equal original length and uniform breaking extension. However variable the breaking load of single strands, the maximum load on the specimen will be taken just before any strand breaks and will be the sum of the breaking loads of all the strands. As a lea test, this would give a constant 100% "lea ratio," but the conditions are not nearly realised in practice, depending on a very unlikely characteristic of the threads, and this ideal furnishes a most unsound basis for analysis of the test.

Case (*b*)—Strands gripped at the ends and under uniform tension. This case is approximated to in a lea test if the ratio of load to extension is very regular, particularly if the lea is wound under a high uniform tension. The load on the specimen F is $(N - n)f$, where N is the total number of strands, n the number broken, f the tension on each strand. If the frequency curve for single-strand breaking load be $y = \varphi(f)$ and N be large,

$$\frac{N-n}{N} = \int_f^\infty \varphi(f).\ df \qquad (14)$$

$$\text{and}\quad \frac{F}{N} = f\int_f^\infty \varphi(f).\ df \qquad (15)$$

F is a maximum when $\dfrac{dF}{df} = 0$, or

$$\frac{1}{N} \cdot \frac{dF}{df} = \int_f^{\infty} \varphi(f) . df - f\,\varphi(f) = 0 \qquad . \quad (16)$$

The tension on each unbroken strand at the maximum load is f or $(a + x)$ where—

$$f = \frac{1}{\varphi(f)} \int_f^{\infty} \varphi(f) . df = \frac{N - n}{Ny} \qquad . \quad . \quad . \quad (16a)$$

for an empirical frequency curve, or

$$h(a + x) = \frac{1 - \Phi(hx)}{2} \cdot \frac{\sqrt{\pi}}{e^{-h^2x^2}} \qquad . \quad . \quad . \quad (16b)$$

for the normal curve. The ratio of the strength per strand to the mean single-strand strength is then—

$$\frac{F}{Na} = \frac{f^2 \varphi(f)}{a} = \frac{N - n}{N} \cdot \frac{f}{a} \qquad . \quad . \quad . \quad . \quad (15a)$$

for an empirical curve,

$$= \frac{1}{\sqrt{\pi}} \cdot \frac{h^2(a + x)^2}{ha} \cdot e^{-h^2x^2} \qquad . \quad . \quad . \quad (15b)$$

for the normal curve. The proportion of unbroken threads is—

$$\frac{N - n}{N} = f\varphi(f) = f . y \qquad . \quad . \quad . \quad . \quad . \quad (14a)$$

for an empirical curve,

$$= \frac{h(a + x)}{\sqrt{\pi}} \cdot e^{-h^2x^2} \qquad . \quad . \quad . \quad . \quad . \quad (14b)$$

for the normal curve.

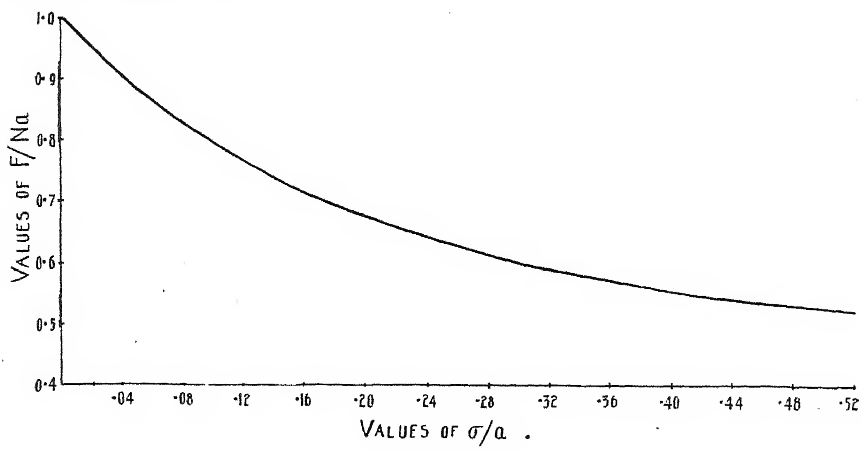

Fig. 4

These equations apply to a continuous frequency curve strictly only when all strength intervals are equally represented in the specimen. The mean breaking load of a number of specimens of finite size will vary about a mean somewhat greater than that given by (15b). This relation, expressed

in terms of the standard deviation, is shown graphically in Fig. 4. Slight differences of tension among the strands may be allowed for by corresponding changes in breaking load, i.e. by adjusting the value of h.

Case (c)—Gripped strands originally of the same length. The extension e of the strands at any moment is uniform, the number of unbroken ends is

$$\frac{N-n}{N} = \int_e^\infty \varphi(e).\,de \qquad (17)$$

where $\varphi(e)$ is the frequency distribution of breaking extension.

The force on the specimen will be affected by any correlation between breaking extension and the load-extension ratio for single strands. Tests made on the Shorter instrument on 45 threads of 36's Sakel yarn (Paper III.) showed that the mean ratios for the survivors after no breaks, the first five lowest extensions, the second five, &c., were ·773, ·770, ·764, ·761, ·760, ·756, ·762, ·769, ·755. It is accurate enough to use an unvarying mean ratio of load to extension, $E = f/e$, when—

$$\frac{F}{N} = E.\,e.\int_e^\infty \varphi(e).\,de \qquad (18)$$

Then F is a maximum when—

$$e = \frac{1}{\varphi(e)}\cdot\int_e^\infty \varphi(e)\,de \qquad (19)$$

and the ratio of strength per strand to mean single-strand strength is given by substituting this value in the formula.

$$\frac{F}{Na} = \frac{E}{a}\cdot e^2\,\varphi(e) = \frac{e^2}{\bar{e}}\cdot\varphi(e) \qquad (18a)$$

This result is identical with the foregoing, except that the frequency curve of breaking extension is substituted for that of breaking load. The decrease in strength per thread for cases (b) and (c) can be found from Fig. 3. Case (c) probably gives the nearest simple approximation to a large number of physical cases, including the lea test, when the threads are gripped so tightly that they do not slip when neighbouring threads break.

Case (d)—Strands maintained at uniform tension and all slip when one breaks. This is realised when a long continuous thread is wound over hooks or pulleys incapable of maintaining differences of tension. The case is fully covered by the formulæ for long specimens.

Case (e)—Strands of uniform original length uniformly extended (gripped) till one breaks, when all slip. This bears the same relation to (d) that (c) does to (b).

The breaking extension is the minimum value among the individual strands and is given by formulæ mathematically identical with those for the breaking load of a long specimen.

If e_r be the mean breaking extension of a specimen of r strands, S_r the standard deviation,

$$e_r = e_1 - vS_1 \text{ and } \frac{S_r}{S_1} = u \qquad (20)$$

The mean ratio of load to extension E may be taken to a first approximation as constant for its variability decreases as $r^{\frac{1}{2}}$ against $r^{\frac{1}{5}}$ for the breaking extension of the whole specimens. Then—

$$E\,e_r = E\,e_1 - vES_1$$

$$\text{or} \quad a_r = a_1\left(1 - v \cdot \frac{S_1}{e_1}\right) \qquad . \quad . \quad . \quad . \quad . \quad . \qquad (21)$$

$$\text{and} \quad \frac{\sigma_r}{a_r} = \frac{S_r}{e_r} = \frac{S_1 u}{e_r} = u \cdot \frac{e_1}{e_r} \cdot \frac{S_1}{e_1}$$

$$\text{or} \quad \sigma_r = u \,.\, E \,.\, S_1 \qquad . \quad . \quad . \quad . \quad . \quad . \qquad (22)$$

Equation (22) is approximate in so far as it neglects the variability of E which may be appreciable on specimens of a small number of strands. To take it into account would involve consideration of the correlation between E and e, and the complication is not justified as the equation is nearly true even for $r = 1$, the variability of load being of the same order as that of extension.

THE LEA TEST

When a lea of yarn is wound and tested without particular care, a rough approximation is made to case (*c*) and case (*e*), varying between them according to adventitious circumstances. If the ends be clamped the approximation to case (*c*) is improved, but the difficulty of obtaining uniform initial tension and of avoiding tearing is so great that actually the results are lower than without clamping. The case is, moreover, much less simple than case (*e*) in correlating with single-thread properties.

If a thread is led over a number of light well-mounted pulleys, a close approximation to case (*d*) is obtained which gives the simplest possible relations, but the method could hardly be applied to more than a few turns. If wound over the usual hooks to a fewer number of turns than a whole lea, and carefully placed so that the threads do not interfere with each other, and if loaded so slowly that the threads can slip without increase of load at the first break, then the conditions are very accurately those of case (*c*), and the relations simple and of useful significance.

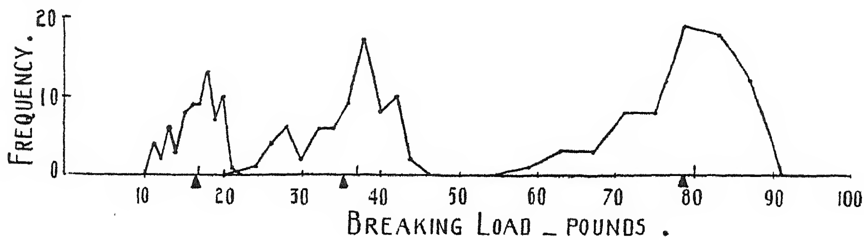

FIG. 5

The friction between threads and hook allows a ratio of tensions of 1·6 between the two sides (Paper I., Appendix 1). This does not allow any material differences of tension at the beginning of loading and the threads slip slightly to adjust any unevenness. The tension developed in stretching varies according to the ratio of load to extension. From the Shorter diagrams of 36's Sakel yarn referred to in case (*c*), the standard deviation of this ratio is 6·4% of the mean. The probable difference of tension between two adjacent threads is then 6·1%, and the probability of differences of 60%

over the tension developed in even the most extensible threads is vanishingly small. The suggested modification of the lea test is therefore a very close realisation of case (*e*).

Negative skewness is introduced by the conditions of this case to the same extent as for long specimens, that introduced by a multiple of 160 being 0·334. The frequency polygons for the strength of 72 leas, half-leas, and quarter leas of 60's West Indian yarn wound off a cheese are shown in Fig. 5. The skewnesses, calculated from the mean and median, are respectively − 0·565, − 0·906, and − 0·463, and, furthermore, they approximate to a smooth curve of the type derived analytically (Fig. 1).

33—THE LEVELNESS OF MULE YARNS

By A. E. Oxley, M.A., D.Sc., F.Inst.P.
(The British Cotton Industry Research Association)

In a paper, "A Gravimetric Method for Investigation of the Variation of Levelness of Yarn" (*J. Text. Inst.* 1926, **17**, T259), S. G. Barker, discussing the subject of the mule draw, says, "In the case of cotton, Oxley found a maximum thickness at the end of each draw, or approximately 70″ apart."

This statement is incorrect, on Barker's assumption that "thickness" is determined by the gravimetric test. The regularity tester measures the diameter of a yarn under a suitable load, and this diameter is primarily dependent on twist hardness, which is definitely periodic, and secondarily on the counts. It would appear that Barker can hardly have recognised the difference between counts and photographic regularity tests as detailed in *J. Text. Inst.* 1922, **13**, T54. Though the roving delivered by the rollers may be such that the bulk of cotton in each element of the stretch is perfectly constant, yet the twist period will persist, those elements of yarn nearest the spindle tip having an unduly high twist and appearing thin to the eye. These thin pieces of yarn give a maximum on the trace of the photographic regularity tester, owing to their greater resistance to compression. Such a yarn, ideal as it may be, judged by a counts test, may give rise to the fabric faults of barring and steepling already well-known and no finishing process can eradicate them. The periodic variation of *twist* was amply confirmed on the oscillating stress tester (*J. Text. Inst.* 1923, **14**, T18).

Barker apparently considers that levelness of yarns can be satisfactorily interpreted in terms of *bulk of cotton*, ignoring completely variations of twist. It should be clearly emphasised that this is not the case and that the maxima of thickness which he mentions are not directly connected with any maxima referred to in work with the regularity tester.

It should also be pointed out that the gravimetric method is by no means original; for counts tests on regularity were made four years ago on yarn specimens 1 in. long, to investigate the inverse correspondence of twist and fibre numbers (*J. Text. Inst.*, 1922, **13**, T172, Plate I., and *J. Text. Inst.*, 1923, **14**, T23, Plate IV.), and not only were thousands of these short specimens weighed on a micro-balance, but the number of fibres in each was counted. As will be seen from a perusal of the papers referred to, the inverse correspondence of twist and fibre number holds roughly, except for those elements of the mule yarn which were near the spindle tip in the draw. This periodic twist is a serious lack of levelness which no counts test will disclose. In short, although the counts, inch by inch, are uniform it does not follow that the yarn is satisfactory for trade purposes. Other tests are necessary.

Lastly, the statement on p. T259, that in the regularity tester "the yarn was drawn between a metal shoe and a *flat plate*" is incorrect. It seems desirable to point out these mis-statements, since they imply a false interpretation of the results published so long ago as February 1922.

34—THE BLEACHING OF WOOL WITH SULPHUR DIOXIDE

A SUMMARY OF THE LITERATURE

By E. F. H. Cook

(The British Research Association for the Woollen and Worsted Industries)

INTRODUCTION

If wool is treated with sulphur dioxide, washed with water, and subsequently reoxidised, it will be found to have undergone certain changes. The natural colouring matter of the wool which is insoluble in water has been reduced, and with the SO_2 forms a water-soluble, colourless leuco compound, which has to be washed out well if the bleach is to be fairly permanent. The process is called "sulphuring," and is the oldest and cheapest method of bleaching wool. It was already practised in the Middle Ages on very much the same principles as it is to-day, and no operation in bleaching has changed so little during the centuries. According to the form in which the SO_2 is applied, either in the form of gas or dissolved in water, one can distinguish between "gas bleaching" and "liquid bleaching," and of these two methods the former is more generally employed.

With regard to the results obtained with either method, it may be said that neither sulphur fumes nor the liquid give a really genuine bleach. The sulphur whites are all more or less unsatisfactory because they are not permanent. The oxygen of the air reoxidises them back to their original condition, an action which is greatly hastened by moisture, sunlight, and air. (It will be noted that the fact that the colour returns does not agree with the statement that the leuco compound must be or can be washed out. Raynes[24a] shows that dry wool forms a yellow compound with SO_2; this may explain the discrepancy.) The rough and harsh handle which the sulphur imparts to wool, and the smell of it, which is extremely difficult to eradicate from the goods, are further disadvantages of the sulphur bleach.

Many of the processes described involve the use of oxidising substances (e.g., permanganate) either before the SO_2 or after to remove the excess. There seems to be little evidence of advantage in these more elaborate methods.

TECHNICAL APPLICATION

The Gas Method

The wool is well scoured to free it from soap and grease, exposed to the gas for from 6-24 hours, according to requirements, then aired and rinsed, treated with oxidising agents if necessary, and again rinsed in water. The foregoing is a general outline of the process, but a number of good descriptions of the same will be found in current text-books, [7, 8, 9, 21, 25, 36, 37], which differ only slightly in details of mechanical equipment or length of exposure to the gas.

The bleaching action of sulphur dioxide on the wool is explained by Bottler[2] in the following way—A colourless compound forms between the colouring matter of the wool and the dioxide, and is removed by washing, as it is liable to undergo decomposition after a time, thus causing the wool to resume its natural colour. He attributes the harsh handle of wool not

to sulphuring, but to rinsing in impure or hard water. Cooper[4] is of the opinion that the SO_2 in some cases decomposes the water present, liberating hydrogen, which in its turn reduces the coloured body.

According to Beech,[1] the gas method is not an effective process, as the colouring matter is not destroyed, but only enters into a chemical combination. Another defect, he states, is that the sulphur volatilises, settles upon the wool, and turns it yellow. To restore the suppleness of the wool, which sulphur bleaching leaves rather hard, the author recommends washing in weak soft soap or soda, care being taken that the alkaline treatment is not so strong as to neutralise the bleaching effect.

Hummel[12] considers that the bleaching action of sulphur dioxide is most probably due to its reducing action upon the natural yellow colouring matter of wool, or perhaps to the formation of a colourless compound with the latter. But the effect is not permanent. Frequent washing in alkaline solution tends to restore the yellow colour of the fibre, which is to be explained according to Hummel[12] in the following way—it either induces oxidation or the colourless bisulphite compound is decomposed and the original colouring matter is precipitated on the fibre.

Meister, Lucius & Brüning[20] point out the disadvantage of the sulphur bleach of only transforming the yellow of wool temporarily into a colourless body, and of acting destructively on many colours if all traces of sulphur dioxide are not removed, but they consider it to be cheaper and easier to operate than any of the oxidation methods. They further state that sulphur whites change their shades considerably in the subsequent processes of milling and steaming if Methyl Violets have been used for tinting.

Heermann[11] is of the opinion that on the whole the gas method is not supposed to be so thorough as the liquid process, but where the gas comes properly into contact with the fibres, it is more effective than the solution. He, too, advocates clean and if possible soft water, as unsuitable water gives wool a harsh handle. To prevent this harshness, he applies a weak soap bath before sulphuring, and adds soda or soap to the rinsing water to neutralise the acid, and at the same time remove the reaction products of the wool dyestuffs. This is especially important as bleaching has only converted the colouring matter into a leuco compound and not destroyed it.

In connection with the effect of sulphur dioxide on wool it is interesting to note Matthews'[17] observation, that besides giving the fibres a harder and rougher handle, it lessens their lustre. He, too, points out the difficulty of removing SO_2 from wool, but thorough washing with iron-free water, or in some cases weak baths of chloride of lime, sodium hypochlorite, potassium permanganate, or hydrogen peroxide should free the fibre from it and restore the pleasant handle. Of these oxidising agents he believes hydrogen peroxide to be the safest. It converts the SO_2 into sulphuric acid, which is easily removed by washing, and, further, there is no danger of an excess injuring the fibre. Chloride of lime, although it neutralises the injurious effect of sulphurous acid, and also increases the affinity of wool for many dyestuffs, gives injurious results if all the chemical is not subsequently removed. In another of his books Matthews[18] discusses the practical impossibility of removing every trace of sulphurous acid by washing, however thorough it may be, as the wool apparently combines chemically with it. Sulphurous acid, he states, holds the pigment in the fibre in a reduced state so that the bleach lacks permanency, and, further, the

presence of sulphurous acid is liable to act injuriously on other colours with which the wool may subsequently come into contact.

Numerous secondary effects of the stoving process are discussed by Schofield,[30] who maintains that some SO_3 is formed at the same time, which combines with the moisture to form sulphuric acid in the fabric, and the concentration of this acid during drying may deteriorate the material.

Ristenpart and Herzfeld[27] allow sulphur dioxide to act on the wool overnight and longer, and especially point out that the goods must be moist, as the dry gas does not bleach. Matthews[18] makes a statement to the same effect, that the wool should be moist, not wet, as the gas only acts slowly on dry wool. He exposes the material to the gas for 10-20 hours. Walland[34] in his description of the gas bleaching method, advocates the presence of sufficient oxygen in the sulphur chamber, otherwise the sulphur dioxide is mixed with sulphur fumes, which condense in cool places and form yellow stains.

According to Bottler[3] the bleaching operation lasts from 6-8 hours, and if necessary is repeated two or three times. Treatment with a warm solution of soda and soap then follows, which removes the excess of acid and (he says) also the converted colouring matter. It also makes the wool supple and soft. This author further remarks that although the soda gives wool again rather a yellowish tinge, this can be removed by sulphuring and washing once more.

With reference to the use of potassium permanganate for oxidising purposes, Matthews[18] recommends great care not to employ an excess beyond that which is necessary for the reaction, otherwise a brown deposit of an oxide or hydrate of manganese will form on the wool. Subsequent treatment with sodium bisulphite, he states, again removes this deposit. Knecht, Rawson, and Loewenthal[15] counteract the small amount of yellow which remains in the wool after stoving, by blueing or tinting with a colour complementary to yellow. A similar method is recommended by Meister, Lucius & Brüning,[19] who pass the wool through a weak soap bath, which for special shades is tinted with suitable blue or violet colours. The bleached material must not be dried at too high a temperature.

Sulphur Stoves &c.

Much of the plant in use to-day is still very primitive. A chamber of four walls and a pan in the corner upon which the sulphur is burnt, constitute the whole equipment, and although newer stoves are better constructed, they still adhere closely to the old system. The most notable modification is that the sulphur is sometimes burnt in a separate compartment, the gas being led or driven by a fan into the bleaching chamber.

An example of this type of generator is the Clayton; the air and gas is continually circulated from the bleaching chamber through the burner and back to the chamber. In this manner a greater concentration of gas is obtainable, and the concentration is easily controlled.

Hummel[12] describes a stove of the above old style, and one in which the operation is made continuous for thinner materials. The latter is provided internally with a wooden frame, having rollers above and below. The roof is lined with lead and heated with steam pipes to prevent condensation. The stove is charged with sulphur dioxide by burning the sulphur inside or preferably outside, and leading it in underneath a false perforated floor. The cloth is introduced through a narrow slit in the wall, passes

under and over the rollers and out again by the same opening. A similar stove is also described by Beech.[1] Further technical details of sulphur stoves are given by Paterson,[22] who holds that they require to be spacious, although not too roomy, in order to give free access to all parts of the yarn, so that full advantage may be taken of the sulphur consumed. If the chambers are built of brick, the walls must be lined with wood, as SO_2 so acts on the bricks and lime as to disintegrate them in time. He also recommends special attention to the heat of the ball used for igniting the sulphur, and the proper admission of air into the chamber. Zänker[37] describes a stove only differing from the above in that the gas is passed underneath the roof instead of the floor. According to the size of the chamber, two, three, or more sulphur pans are used, so that the sulphur does not sublimate, but burns completely. A vessel containing water should be placed inside the chamber to produce the necessary moisture. Bottler[3] recommends passing wool fabrics &c., which are to be bleached, slowly through the sulphur stoves instead of hanging them up, and describes a stove with ventilation holes, which open and close automatically with the varying pressure. By covering the sulphur pans with a lead-coated shield and a piece of felt, sulphur is prevented from settling on the goods.

A good illustration of a continuous sulphur stove is given by Reiser.[25] It really consists of four chambers—(1) containing the sulphur pan, (2) a chamber where the sulphur fumes are distributed and pass through an opening into (3), the actual sulphur chamber, at each side of which are continuously rotating rollers, and (4) a ventilator. In some sulphur stoves the motion of the goods is not a horizontal but a vertical one, and in the latter case the fumes rise to the top and are distributed more easily.

It may be noted that when a continuous fabric is to be treated the method of passage over rollers offers advantages. If also one of the methods of recirculating the chamber gases through the burner be used, thus obtaining a high concentration of gas, then the time necessary for treatment may be very brief.

Matthews,[17] in his detailed account of various forms of bleaching chambers emphasises the necessity of providing suitable means of ventilation and heating coils to prevent drops of condensed acid forming on the roof. The presence of metals in these rooms should be avoided, as acid vapours forming therein will rapidly attack them, and the products dropping on the wool will cause stains. He further describes a convenient apparatus devised by Shaw for bleaching wool materials with compressed sulphurous acid gas in an airtight vessel, where it is supported on a perforated beam. It consists of a cylinder containing the liquid sulphurous acid which is connected to an expanding chamber. This in turn is connected with a cylinder through which a perforated pipe leads up through the material to be bleached. The air having been exhausted from the expanding chamber, sulphurous acid is admitted until a pressure of about one atmosphere is attained. Shaw also describes this same apparatus in his patent (1901).[32]

In some old patent specifications the gas method of bleaching wool &c. is described as follows by Dale and Dale (1866).[5] The fabrics are placed in an airtight vessel into which sulphurous acid produced by burning sulphur in air or by heating sulphuric acid and charcoal, is introduced either alone or mixed with steam. Piece goods may be wound on a perforated pipe, and the sulphurous acid forced through them, either alone or mixed with

steam, or water may be supersaturated with sulphurous acid and used instead of the gas. Sachs (1876)[28] patented the following procedure. Wool after washing with a weak solution of chlorine is treated with a solution of potassium permanganate, and then subjected to the action of sulphur vapours in a closed chamber. The materials are then washed with a weak alkaline solution. In some cases a small quantity of magnesium sulphate is added to the permanganate solution. A patent taken out by Margotin (1909)[16] describes an apparatus and means of preventing alteration in the fibre, or the production of yellow stains, due to the action of the air, and also to avoid the escape of SO_2 into the atmosphere. In addition to the usual closed vessel this comprises—(1) The driving of SO_2 out of the vessel into water or an absorbent solution of soda or lime by compressed air; and (2) prior treatment with a solution of potassium permanganate, hydrogen, or other suitable peroxide, to prevent any harmful action by the compressed air.

The Liquid Process of Bleaching

For this purpose aqueous sulphurous acid or sodium bisulphite solution are usually employed, and bleaching by means of the liquid method is considered to be as powerful as bleaching with sulphur dioxide gas. The goods are worked and steeped in a bath containing bisulphite of soda, sulphuric or hydrochloric acid, and *iron-free* water, treated with oxidising agents and tinted with alkali violet or some other colour. If the whites are required to withstand milling, the use of indigo in the bleaching bath or afterwards is advisable. In a paper on bleaching with sulphurous acid or bisulphite of soda (*J. Soc. Dyers and Cols.*),[38] the suitability of both agents for the purpose are compared, and the bisulphite of soda is considered to be more suitable, as it dissolves the brown shade of manganese oxide from the fibre more easily.

The whites obtained with the liquid method are not more permanent than those produced by sulphur dioxide, but a better clearance of the sulphur smell is possible (*Text. Rec.*).[39] Matthews,[17] however, is of the opinion that although the whiteness produced by the liquid process is of the same degree as that obtained with the stoving method, it is more permanent, and when dry the wool is free from the smell of sulphur. The writer assumes that this greater permanency of the white is probably due to the better penetration of the bleaching agent into the core of the fibre.

Liquid bleaching is not any more perfect than gas bleaching, according to Beech,[1] as the colour is liable to return on washing with soap or alkalis. It is, however, free from the defect of producing yellow stains. Paterson[22] considers the wet process to be the best theoretically, but the bleaching action seems to take longer than by the gas method. Zänker[37] and Murphy[21] both state that the liquid bleaching method is generally preferred to the SO_2 method, especially for piece goods, as a better control during the process is possible. Meister, Lucius & Brüning[19] find that the shades are not as pure as those obtained by bleaching in sulphur chambers.

Details of the bisulphite process are given by Matthews[17] as follows—The material is steeped for 6-10 hours in a sodium bisulphite bath of about 2° Tw., and subsequently in a bath of sulphuric acid at 1° Tw., which renders the bleaching complete. The whole process lasts from 6-24 hours. Treatment with chloride of lime or other oxidising agents removes the last traces of sulphurous acid. The writer points out the necessity of thorough scouring and hydro-extracting before bleaching, as cloth, if too wet, will not take

up the bleaching liquor properly, and if too dry the bleaching is uneven. Bottler[2] advocates a solution containing sodium bisulphite and hydrochloric acid, the operation being equivalent to bleaching in a solution of common salt saturated with sulphur dioxide. Beech[1], too, recommends a weak hydrochloric acid bath after steeping in a bisulphite solution for one hour, as this liberates sulphur dioxide, which in a nascent condition is more powerful than if it were already free.

With regard to the strength of the solutions to be used, Hummel[12] is of the opinion that bleaching is more effective by leaving the wool in a sodium bisulphite solution of 20° Bé for 10-15 hours, and then immediately treating with sulphuric acid of 4° Bé, than by bleaching in dilute solutions. Zänker[37] uses three baths. A preliminary bath containing potassium permanganate and soda, a bath 2-3% of sulphurous acid or sodium bisulphite of 3°-5° Tw., and a second bisulphite bath or an almost boiling solution of oxalic acid. In an anonymous paper on sulphur bleaching (*Text. Rec.*),[39] it is suggested that by giving the acid bath separately the method is far more effective than by combining it with the bisulphite bath, as then the acid liberates sulphurous acid within the fibres themselves. A recent patent by Griesheim-Elektron claims the use of sodium bisulphite of 0·5 to 1·0 B for 2 to 5 minutes.

According to an earlier patent by Smith (1875),[33] wool is subjected to the successive action of warm oxidising baths, followed by washing with alkaline sulphites and warm or cold liquors of bisulphites or sulphurous acid. After being subjected to the action of dissolving agents or oxidisers, the goods are sufficiently bleached to receive any dye. Sahlström and Parr,[29] in their patent (1892), treat wool successively with a solution of permanganate of potash, air, liquid, or gaseous sulphurous acid, water, and a current of oxygen or ozonised oxygen. Jardine and Nelson,[14] in a more recent specification (1914), bleach textile fibres under pressure with magnesium or sodium bisulphite, the liberated gases being removed in order to prevent deterioration of the fibre by the liberated sulphur dioxide.

Many other accounts of the bisulphite method which only vary in a few details are to be found in current literature by Matthews,[18] Hummel,[12] Knecht, Rawson and Loewenthal,[15] Paterson,[22] Meister, Lucius and Brüning,[19, 20] Walland,[34] Heermann,[11] Bottler,[3] Ganswindt,[9] Schreiber,[31] E. P. Paterson,[24] &c.

Sulphurous acid can also be substituted by sodium hydrosulphite, and Matthews,[17] Bottler,[2] Knecht, Rawson and Loewenthal,[15] Dommergue,[6] *Text. Rec.*,[39] and patent specification Imray,[13] have described processes of this kind. Small quantities of finely ground indigo, thin milk of lime until alkaline, and acetic acid are usually added to the hydrosulphite vat. The indigo is converted into indigo white, and absorbed by the fibres in this condition, the blue colour being regained on exposure to air. Knecht, Rawson and Loewenthal[15] immerse the goods in the above vat for 12-24 hours, while Matthews[17] considers soaking for 6-8 hours in a hydrosulphite solution at about 2° Tw. sufficient. Dommergue[6] points out the necessity of washing and rinsing the wool out of contact with air during the process, otherwise heating takes place and the material is damaged. He further suggests that if the pieces are marked, they should be passed through a bath of dilute hydrochloric acid.

The use of hydrosulphite of soda in conjunction with barium chloride for the purpose of bleaching wool is described by Graham and Cope in their

patent.[10] The goods are bleached by immersing in a solution obtained by treating sodium bisulphite with zinc powder, decanting, and adding barium chloride paste to the liquid, and then washed in potassium permanganate.

Bottler[3] and Zänker[37] give details of the method of bleaching with hydrosulphurous acid as follows—The wool is treated for 12-24 hours in a bath of dilute hyposulphite (3°-4° Bé) and acetic acid, exposed to air, washed and dried.

Wirth (1876)[35] has patented the following procedure—The wool is passed through a bath of indigo, and is then placed in a vat containing hydrosulphite and some acetic acid, air being excluded. The indigo is reduced to indigo white, which on exposure to air becomes permanently blue, neutralising the yellow of the wool. The bath may then be used for a second operation with addition of a further quantity of hydrosulphite. The fibre is taken out and hydrochloric acid added until sulphurous acid gas is given off from the sulphites present. The fibre is replaced and bleaching completed by the sulphurous acid. After-treatment with acetic acid finishes the process. Wirth suggests the use of neutral hyposulphite for bleaching wool of a very yellow colour.

INVESTIGATIONS ON THE CHEMISTRY OF THE PROCESS

On the subject of fixation of sulphur dioxide by wool, during the bleaching process, some interesting investigations have been made by Reychler,[26] from the results of which he concludes that the amount of gas fixed by wool depends partly upon (*a*) chemical combination, but (*b*) mainly upon absorption (solution) of the gas by the fibre.

The following is the method which Reychler[26] used for this determination—The material was placed in a dry atmosphere of sulphurous acid, mixed in various proportions with air. C and c respectively denote the number of molecules of SO_2 per kilogram of wool and per litre of gas. In the case of fat-free wool containing 11·4% of water, the relationship between C and c is given by the equation $C = 0{\cdot}88 + 44{\cdot}7c$, provided c is greater than about 0·005 molecules per litre. When the concentration of sulphur dioxide is smaller than this, the amount absorbed is less than that required by the equation, and the difference between the two quantities increases as the concentration diminishes. This shows that the quantity combined increases first with the concentration, but attains a maximum, represented by 0·88 molecules of sulphur dioxide per kilogram of wool.

Some figures obtained by Raynes[24a] agree fairly well with those of Reychler, but he can find no proof of the presence of a chemical compound in measurable amounts.

Paterson,[23] in his paper dealing with the affinity of wool for SO_2, writes that sulphur dioxide is retained so strongly by wool that drying stoved yarns at 160°-212° F. will not remove it. Yarns wound on bobbins were found to retain SO_2 after 12 years on the inside where it is not exposed. When he exposed sulphured yarns to strong direct sunlight for 10 days, he found that nearly two-thirds of the adsorbed SO_2 changed into sulphuric acid. A sample of ordinary sulphured yarn after heating for four hours to 160° F. to expel the excess of sulphur dioxide, was steeped for 12 hours in cold water and gave up 0·56% sulphur dioxide, but if exposed to sunshine will yield to the water only 0·17%, the rest being in the form of sulphuric acid.

35—THE BLEACHING OF WOOL WITH SULPHUR DIOXIDE AND SULPHUROUS ACID AND A NOTE ON THE PRESENCE OF A CARBONYL GROUP IN WOOL

By JOHN L. RAYNES

(Holder of Fellowship at University College, Nottingham, *granted by* The British Research Association for the Woollen and Worsted Industries)

THEORETICAL CONSIDERATIONS

SUMMARY AND CONCLUSIONS

The bleaching of wool by sulphurous acid has previously been attributed to (*a*) the conversion of the colouring matter into a soluble substance, (*b*) reduction to a colourless compound, (*c*) combination to form a colourless compound.

It is shown in the present communication that at least two distinct components of wool combine with sulphur dioxide. The one of these, apparently itself colourless, gives a lemon-yellow product, which may be prepared from nearly dry wool, and is only produced when a high concentration of sulphur dioxide is used; this substance is very unstable, being completely decomposed in a vacuum. This yellow body and this reaction do not seem to be connected with the bleaching effect. It may be suggested that some colourless amino-compound of the wool is converted by combination with sulphur dioxide (possibly only in the presence of a trace of water) into a coloured quinonoid salt, just as colourless amino-derivatives of triphenyl carbinol are transformed into coloured compounds by interaction with acids.

The other component of wool which combines with sulphur dioxide does so only in the presence of appreciable quantities of water, and is possibly a coloured carbonyl compound which gives a colourless additive product

$$>C\begin{cases}OH\\O{\cdot}SO{\cdot}OH\end{cases}$$

This substance is relatively stable in a vacuum, but is very slowly decomposed on exposure to light and air, the wool being then debleached; it is slowly decomposed by prolonged washing with water, and very quickly by alkalis.

The bleaching of wool with sulphur dioxide in the presence of moisture does not depend to any appreciable extent on the reduction of any component by the addition of hydrogen and simultaneous formation of sulphuric acid.

The presence of carbonyl compounds in wool seems to be established by the behaviour of the material towards hydroxylamine and semicarbazide, but from the fact that wool bleached with hydrogen peroxide still reacts with hydroxylamine, it would seem that there are both coloured and colourless carbonyl-compounds in the fibre.

From a very comprehensive survey of the literature dealing with the bleaching of wool by sulphur dioxide and sulphurous acid,* it is clear that

* As facilities were not available in Nottingham for a thorough search of the literature, the British Research Association for the Woollen and Worsted Industries kindly placed at the author's disposal an epitome by Miss Cook of some forty papers and text-books on the subject; the author wishes to express his gratitude for this assistance.

very little is known about the chemical changes which occur in these operations. Some writers (Bottler, "Modern Bleaching Agents and Detergents") suggest that the natural colouring matter of the wool, which is insoluble in water, is converted into a soluble substance, which is removed when the material is subsequently washed. According to Cooper ("Textile Chemistry"), this conversion is due to reduction, involving the simultaneous oxidation of the sulphurous acid, but Hummel ("The Dyeing of Textile Fabrics") suggests that the sulphurous acid combines with the colouring matter to form a colourless product.

From a theoretical point of view, no other suggestions of importance have been made, and any further reference to the original papers or text-books would therefore be of little value; the matters there dealt with concern rather the non-permanency of the sulphur bleach, the relative merits of the dry (gas bleaching) and wet (liquid bleaching) processes, the effect of the treatment on the properties of the wool, and other questions of practical importance, which throw no light on the chemistry of the process.

The first experiments which were made had for their object to ascertain whether any component of wool does or does not combine with sulphur dioxide. For this purpose unbleached wool, dried at 100° C., was treated with dry sulphur dioxide in the absence of air; instead of being bleached, the wool turned a distinct lemon yellow colour, which persisted even after prolonged action. A similar development of colour also occurred when the wool was treated with a sufficiently concentrated solution of sulphurous acid. As it is difficult to conceive that such an intense coloration could be produced by simple adsorption, it must be concluded that chemical combination occurs between the sulphur dioxide and some component of the wool. The yellow compound so formed, however, is most unstable, since, when the coloured wool is placed under highly reduced pressure it regains its original (unbleached) appearance; the same result occurs when pure nitrogen, hydrogen, oxygen, or carbon dioxide is passed over the yellow material, and also when the latter is treated with a sufficient quantity of air-free water. It appears therefore that the yellow additive compound dissociates or decomposes even at ordinary temperatures. It may also be inferred that the yellow compound is not formed from that colouring matter which is rendered colourless in sulphur bleaching; because, whereas both wet and dry wool give the yellow product, the former only is bleached when the sulphur dioxide is subsequently removed under reduced pressure. In other words, the disappearance of the lemon yellow colour is not necessarily accompanied by the bleaching of the wool; whether the latter is bleached or not depends on some other change which has taken place previously, during the actual development of the yellow colour. In order to try and obtain further evidence of chemical combination, very careful experiments were made on the absorption of sulphur dioxide by wool both in the "dry" condition and in the presence of known quantities of water. For this purpose it was necessary to devise an apparatus consisting entirely of glass, because it was found that rubber stoppers and connections absorbed appreciable quantities of sulphur dioxide.

The wool which was employed was first extracted with ether in a Soxhlet apparatus, then thoroughly washed with water at 50° C., extracted with pure alcohol, and dried at 103° C. in a conditioning oven.* For those experiments in which moist wool was used, a known weight of the dried materials was then exposed to moist air or damped with water; from the

gain in weight the percentage of moisture in the product could be ascertained. The absorption experiments were carried out under atmospheric pressure, pure dry sulphur dioxide being used; most of the gas was absorbed during the first ten hours, but not until about twenty-four hours had elapsed was absorption practically complete.

From the results of four concordant experiments it was found that one gram of "dry" wool at 17° and 760 mm. pressure absorbs 55 c.c. of sulphur dioxide. The presence of a small quantity of added water did not make any appreciable difference to the result, but when the wool carries 75-100% of its own weight of added water, the volume of gas absorbed, calculated for one gram of "dry" wool, increased to 90 to 102 c.c From the average value thus obtained in all the experiments it was found that the increased absorption which occurs in the case of the wet wool corresponds very closely with that which should be observed if the additional volume of gas is merely dissolved in the water present. Thus one gram of "dry" wool, plus 0·75 gram of water, absorbs 89 c.c. of sulphur dioxide. But 0·75 gram of water at 17° and 760 will dissolve 35 c.c. of the gas; subtracting this volume from the total, the absorption due to the wool is 54 c.c., a volume almost identical with that obtained with "dry" wool and with wool containing not more than about 2% of additional moisture.

As it is highly probable that the weight of the sulphur dioxide which acts chemically on the coloured components of wool is very small compared with that of the wool, it was not very likely that any conclusions could be drawn from the final results of such absorption values, since even the "dry" wool would contain water sufficient to catalyse chemical action; for this reason the *rate* of absorption was also studied, and at the commencement of each experiment readings were taken at intervals of fifteen seconds, the absorption values being then plotted in the form of curves. It was hoped that in this way some evidence of chemical combination might be forthcoming, but this was not the case; the regular parabolic curves which were obtained showed no initial irregularities such as might be taken to indicate a rapid chemical combination.

Reychler (*J. Chim. Phys.*, 1910, 8, 3) exposed wool containing 11% of water to mixtures of sulphur dioxide and air of varying and known concentrations, and suggested that his results afforded some indication of chemical combination to a maximum extent of 0·88 mol. of sulphur dioxide per kilogram of wool. The author's observations do not substantiate Reychler's suggestions in this respect, although the experimental absorption values are not discordant. Thus the total maximum absorption, chemical and physical, which Reychler observed was 64 c.c. per gram, compared with about 60 c.c. found by the author. The difference between these

* I am informed by the Director of the British Research Association for the Woollen and Worsted Industries that work which has been carried out and is still in progress shows that commercially "dry" wool may still contain from 1% to 2% of moisture. The commercial method of determining "regain" involves heating the wool in air to a standard temperature above 100° C. The Bradford Conditioning House uses a temperature of about 115° C. (235°-240° F.).

If wool be heated however in dry air (dried by passage over the usual drying agents) there is a further loss of from ½% to 2%.

In the present paper the samples were heated to 103° C and may therefore be assumed to have contained up to 2% of moisture.

I am unable to continue this work at present but the action of SO_2 upon chemically dry wool might repay study at other hands.

figures is probably due to differences in the methods of scouring the wool and to differences in the original samples themselves; it is quite conceivable that wools from different sources would show different absorption values.

In spite of the negative, quantitative results described above, qualitative experiments showed distinctly that the bleaching of wool with sulphurous acid involves the chemical combination of the acid with some component of the material. When moist wool, bleached with sulphur dioxide, is subsequently washed well with several portions of distilled water and then left in a vacuum over caustic potash during a period of about two weeks, it undergoes no visible change; but when it is then treated with dilute sulphuric acid it is partially debleached, and a distinct smell of sulphur dioxide can be detected. It may be concluded therefore that one factor in the bleaching of wool with sulphur dioxide is a combination of a coloured component of the material with the gas, or more probably with sulphurous acid; if the latter merely combined with some colourless amino-acid or other basic substance to form a sulphite, the decomposition of such a salt would not be accompanied by a debleaching effect. It seems probable therefore that the coloured substance which combines with the sulphurous acid is quinonoid in constitution, or at any rate a carbonyl compound (see later p. T383); the additive product, moreover, contrary to what seems to be assumed by some writers, is obviously only sparingly soluble in cold water.

Attempts were next made to find out whether, in addition to the fixation of sulphurous acid, there was any reduction of a coloured substance to a leuco compound; if such a change occurred, sulphuric acid must also be produced, $H_2SO_3+H_2O=H_2SO_4+2H$, and its presence, after bleaching, if established, would lend strong support to the view that a leuco-compound is formed.

Since sulphur dioxide is oxidised by atmospheric oxygen, and is appreciably decomposed by light, giving sulphur, sulphuric acid, and certain thionic acids, these experiments were very troublesome; but apparatus was devised in which wool, which had been previously extracted with alcohol and ether and then well washed with a dilute solution of sodium carbonate until free from sulphates, was treated with pure sulphur dioxide in glass vessels coated with black enamel. The occluded oxygen in the wool and the atmospheric oxygen in the apparatus were removed by filling the whole system with pure hydrogen and then exhausting, these operations being repeated six times before admitting the sulphur dioxide; the hydrogen was freed from oxygen by passing it through three wash bottles containing an alkaline solution of pyrogallol.

After displacing the hydrogen by pure sulphur dioxide and leaving the wool in contact with the gas for about twenty hours, the sulphur dioxide was removed as far as possible by prolonged evacuation; an air-free 4% solution of sodium carbonate was then admitted into the apparatus to extract from the wool any sulphuric acid which had been produced, and the extract was run into excess of dilute air-free hydrochloric acid; the acid solution was then evaporated almost to dryness under reduced pressure. All these operations were carried out in the closed glass apparatus in absence of oxygen and of light.

The concentrated acid solution was next diluted and filtered (in the air) in order to free it from traces of sulphur, produced by the interaction of sodium sulphite and sodium sulphide, the latter of which is formed by the action of sodium carbonate on the wool; the filtered solution was then

treated with barium chloride solution, and the weight of the precipitated barium sulphate determined.

Four very concordant experiments gave an average of 0·023 gram of sulphuric acid when the weight of the wool, containing 13 per cent. of water, was 50 grams; or 0·053 gram of sulphuric acid per 100 grams of "dry" wool. Further experiments showed, however, that it is very doubtful whether even the small quantity of sulphuric acid which was found in the experiments just described had any connection whatever with the bleaching of some coloured substance, because if this acid had been produced as the result of the formation of some leuco-compound, a repetition of the experiment with the same sample of wool, now bleached and left in the air-free apparatus, should give a much smaller quantity of the acid or none at all. A second treatment was therefore carried out exactly as before, except that no hydrogen was used, because there was no air in the apparatus; the quantity of sulphuric acid obtained in this second treatment was practically the same as in the first, and in fact the same wool, treated ten times with sulphur dioxide in the total absence of oxygen, gave each time approximately the same amount of sulphuric acid as in the first experiment. An obvious explanation of these results would be, of course, that oxygen gained admission during the experiment, owing to defective apparatus or that the sulphuric acid was contained in the reagents which were used; several blank experiments were therefore carried out, using a little concentrated solution of sodium carbonate in the place of the wool, all other conditions remaining unchanged; not a trace of sulphuric acid was produced in any case. No satisfactory explanation of this formation of sulphuric acid can be advanced, but the conclusion seems to be justifiable that the bleaching of wool with sulphur dioxide does not involve the addition of hydrogen to a coloured substance. This conclusion is confirmed by the fact that when unbleached wool is well padded with finely divided magnesium and then placed in dilute acid until all the magnesium has dissolved, no bleaching effect whatever is observed; wool left during 24 hours at ordinary temperatures in a solution of formalin appears to be bleached to a slight extent, but under all conditions which we tried the action of formalin is far less than that of sulphur dioxide.

The Presence of a Carbonyl Group in Wool

Up to this stage the experiments seemed to show that the bleaching effect of sulphur dioxide was caused by the addition of sulphurous acid to some coloured component of the wool. Since direct combination with sodium hydrogen sulphite is a property of the carbonyl grouping, it seemed probable that, as already suggested by Gebhard (*Jour. Soc. Chem. Ind.*, 1914), some ketonic compound in the wool is converted into a colourless additive product—

$$>C\begin{cases}OH\\O.SO.OH\end{cases}$$

This view would explain several facts observed by the author, namely, that the presence of small quantities of alkali improve the quality of the bleaching obtained with sulphur dioxide; that when bleached wool is treated with dilute alkalis or soap, it almost immediately reverts to its original colour, even in the complete absence of air; and when bleached wool is boiled with water, debleaching occurs with evolution of sulphur dioxide. On the other hand, it would be contrary to the author's observation that

bleaching with a concentrated solution of sodium hydrogen sulphite is less effective than with sulphurous acid, since the former, apparently, combines with ketonic compounds more readily than the latter.

In order, then, to obtain some evidence as to the presence of the carbonyl grouping, unbleached wool was heated under a reflux apparatus during four hours with an alcoholic solution of hydroxylamine. At the end of that time the wool was removed, pressed, and thoroughly washed with warm distilled water, dilute acetic acid, and again with water. The treated wool and a sample of the original material were then dried at 100° in the same oven, and the percentage of nitrogen determined in each by the Kjeldahl method. The results were as follows—

		Original Wool		Treated Wool		Average Difference
Nitrogen%	...	17·72	...	18·0	...	0·3
	...	17·61	...	17·95	...	

A second series of experiments with a different sample of wool, carried out exactly as before, gave the following results—Nitrogen%, average difference, 0·185.

The increased percentage of nitrogen in the treated material is no doubt very small, but seems to be too large to be due to experimental error. If it were assumed that the carbonyl compound in the wool has a molecular weight of 200 (a purely arbitrary number), the above increase in the percentage of nitrogen would correspond with that required for about 4% of such a compound.

That the increased nitrogen content of the wool is due to a reaction with hydroxylamine having taken place, and not merely to an adsorption, seems to be proved by the following facts—The treated wool gives with an aqueous or alcoholic solution of ferric chloride a deep violet colour, and it does so even when it has been soaked in warm dilute hydrochloric acid for a prolonged period and then washed with water; only after it has been heated with concentrated hydrochloric acid does it cease to give a coloration with ferric chloride, but at the same time the fibre is very much disintegrated.

As the presumed formation of an oxime indicated the presence of a carbonyl compound in wool, an experiment was next made to ascertain whether the carbonyl compound was or was not contributory to the colour of the raw material. For this purpose a sample of pure unbleached wool was treated with a neutral 2-volume solution of hydrogen peroxide during two days, and was then thoroughly washed; this bleached material was then treated exactly as before with an alcoholic solution of hydroxylamine, and subsequently washed well with a alcohol, water and dilute acetic acid. When treated with ferric chloride, this wool gave a violet coloration, which, so far as could be ascertained, was of exactly the same shade as that produced by the oximated wool, which had not been treated with hydrogen peroxide. It must be concluded, then, that the colouring matter in wool which is oxidised by hydrogen peroxide is not the carbonyl compound which reacts with hydroxylamine.

If the interaction of wool and hydroxylamine is the normal change which occurs in the case of a carbonyl compound $>CO+NH_2{\cdot}OH \longrightarrow C{=}N{\cdot}OH + H_2O$, the treatment of wool with semi-carbazide should give a semicarbazone $>C{=}NH{\cdot}NH{\cdot}CO{\cdot}NH_2$, and the increase in the percentage of nitrogen should be approximately three times as great as in the case of hydroxylamine. Two samples of unbleached wool were divided into two parts;

one part of each was steeped in a warm alcoholic solution of semi-carbazide during about 24 hours, and was then squeezed out and thoroughly washed with alcohol, warm water, dilute acetic acid, and water again, successively. The treated samples were then dried in the same oven as the untreated samples, and all four were analysed—

	Untreated Wool		Treated Wool		Difference
Sample A—Nitrogen %	18·20	...	19·1	...	0·9
	18·20	...			
Sample B—	18·12	...	18·87	...	0·8
	18·03	...			

These results afford a very satisfactory confirmation of those obtained with hydroxylamine, and seem to show conclusively that one or more of the components of wool is a carbonyl compound.

The author is greatly indebted to Prof. Kipping, F.R.S., of University College, Nottingham, for the constant interest which he has taken in this work.

36—THE SULPHUR CONTENT OF WOOL PART I.—INHERENT VARIATIONS ACCORDING TO THE TYPE OF WOOL

By J. Barritt, B.Sc., A.I.C., and A. T. King, B.Sc., F.I.C.
(The British Research Association for the Woollen and Worsted Industries)

SUMMARY

The sulphur content of a number of different wools has been determined. A review of the methods available for the determination of sulphur is given, and of these the Carius method is regarded as the most suitable for a substance of the nature of wool, and this method has been used throughout the present work. A modified method for the determination of moisture content, suitable for small samples, is described, and it is shown that regains determined by this method of thorough drying are somewhat higher than those obtained by use of the commercial conditioning oven. Incidentally, it is shown that if a kempy wool, e.g. a Blackface wool, be separated into two grades, say, fine non-kempy and coarse kempy, the regains of the two fractions are the same. It is shown that there is an inherent variation in the sulphur content, according to the type of wool. Generally speaking, finer qualities show a higher sulphur content than coarser qualities. There are also definite variations between different wools of the same quality and breed, and in pedigree flocks the sulphur content varies with different animals. Variations occur in different parts of the same fleece, particularly in coarser varieties, and in the same animal there are indications of variation of sulphur content in different shearings. Kempy wools show a lower sulphur content than non-kempy wools. The lowest value so far obtained is with a sample of coarse Turkey mohair. The sulphur content in relation to a number of factors is under investigation.

INTRODUCTION

The principal constituent of wool is keratin, which belongs to the class of proteins known as scleroproteins. Its composition and properties have been dealt with in a previous paper (Barritt, *J. Text. Inst.*, 1926, **17**, T111). Keratin undoubtedly varies somewhat in composition according to its source, and its sulphur content appears to be particularly sensitive in this respect.

Sulphur may be regarded as the most characteristic constituent of wool substance, and its presence distinguishes wool and hair from certain other proteins. It was therefore felt that a careful investigation of the sulphur content of different types of wool might afford valuable information both from the scientific and commercial standpoints. According to the literature the sulphur content of wool and similar materials (i.e., keratin substances) appears to vary between the limits of 0·7% and 5% (Bourquelot, *Pharm. Journ*, III. 19, 1035), but it must be remarked that many of the determinations of sulphur recorded have been indirect, being estimated from the yield of cystin obtained on hydrolysis of the keratin by acids. Such results are very questionable, since the method depends on all the sulphur being obtained as cystin, and in addition it is probable that much of the cystin obtained was far from pure, the preparation of pure cystin in quantitative amount from a keratin being a very difficult operation.

Previous work on the subject of the sulphur content of wool has been summarised by Trotman and Bell (*J.S.C.I.*, 1926, **45**, 12T). They were

unable to confirm the varying percentages of sulphur found by different workers, and concluded that the sulphur content of wool varies within quite narrow limits. Their published results given for three wools are—

	Max.		Min.		Mean	
Leicester wether	3·41	...	3·00	...	3·29%	Average 3·22%
Leicester hog ...	3·26	...	3·02	...	3·17%	
Black face ...	3·32	...	2·90	...	3·20%	

and they also give the percentage of sulphur in a low grade web as 3·24%. Their conclusion is as follows—"Consideration of the above results indicates that there is very little variation in the percentage of sulphur in purified wool, and that 3·4% is probably the maximum value."

It is not clear from the above table whether the maxima and minima, e.g., in the case of the Leicester wether, viz., 3·41% and 3·00% refer to sulphur determinations on the same fleece, or to determinations on different fleeces. In the event of the first supposition being correct, the results suggest that the method used, viz., the "Denis-Benedict" method, is not sufficiently accurate for the determinations of sulphur in a substance of the nature of wool, and if the second supposition be correct the variations are far from being insignificant.

Possible variations in the sulphur content of wools, assuming no inherent variability, may be caused to some extent by—

(1) The mode of preparing the samples.

(2) Neglect of variable regain under different conditions.

(3) Influences to which the fleece may have been subjected prior to shearing.

Under this heading are the possible effect of dips, especially sulphur dips, on the sulphur content, and the effect of weather.

Some sorption of sulphur may possibly occur with sulphur dips, but this is unlikely to cause actual addition of sulphur to any appreciable extent, since the fleece is very short when dipped.

Regarding the effect of weather, Bergen (*Textilberichte*, 1925, **6**, 745, *J.S.C.I.*, 1926, **45**, B 312) has pointed out that wool exposed to light becomes acid, due to conversion of some of the sulphur present into sulphuric acid. It is probable that the main portion of the fleece will be protected from this action, and that the total sulphur will only be very slightly affected.

It is intended to go further into this question, which, however, is outside the scope of the present paper, the values given in which refer only to the total sulphur content.

Also the normal sulphur content of wool cannot be safely ascertained from any processed wools, and *wools that have been scoured, crabbed, &c., will be separately examined.

While it is essential to remove dirt and wool fat, both of which are liable to contain sulphur, it is preferable to avoid soap or alkali in the scouring, and to use solvents free from sulphur. Further, wool has the power to absorb both sulphur dioxide and hydrogen sulphide, and undue contact with laboratory fumes must be avoided. Any variation in the moisture content will naturally give different values for the sulphur content. It is unfortunate that in much of the work published on the composition and properties of wool, the moisture content of the material used has not been

* In this connection it may be noted that blending of wools will tend to average out any variation, and that analyses of tops or cloth or web can be of little value in investigating inherent variations.

accurately specified. In the present paper it is shown that the sulphur content of wool is variable, and the variability is inherent, i.e., the sulphur content of one type of wool may, and in general does, differ from the sulphur content of another wool.

Methods of Determination of the Sulphur Contents of Wool

In any method involving the determination of sulphur in wool it is essential to know the moisture content of the wool at the time of weighing out the sample to be used. In the present work this was achieved by bottling samples for sulphur analysis, and at the same time bottling a sample for the determination of the moisture content of the wool (see below), the wool being previously stored in the humidity room, which was kept at a definite relative humidity. It was thought preferable to adopt this method rather than use a dried-out sample for the determination of the sulphur content for two reasons—

(1) Wool possesses the property of picking up moisture very rapidly, and is therefore difficult to work with in a dry condition; and

(2) To guard against the possibility that wool on drying out may lose volatile sulphur compounds, though this from experiments carried out appears to be improbable.

Almost all methods used for the determination of sulphur in organic compounds involve the oxidation of the sulphur to sulphuric acid and subsequent precipitation as barium sulphate. In the precipitation of barium sulphate from a solution containing free or combined sulphuric acid it is desirable to have no tervalent metals present, and it is found that when the amount even of a bivalent metal becomes relatively large in comparison with the amount of sulphuric acid present, the error arising from occlusion is likely to be large. On similar grounds the presence of nitric or chloric acids is undesirable.

In practice methods of determining sulphur may be divided into two groups—

(*a*) Dry or fusion methods.

(*b*) Wet methods.

An outline of these is given below.

Fusion Methods for the Determination of Sulphur

Liebig's Method.—A mixture of 8 parts of potassium hydroxide and 1 part of potassiumn nitrate is melted in a silver crucible with the addition of a little water. After cooling the substance is added and the contents of the crucible cautiously heated, and the mixture frequently stirred by means of a silver wire until the organic substance is completely decomposed. The melt is allowed to cool, extracted with water, acidified with hydrochloric acid, and the sulphuric acid precipitated and estimated as barium sulphate.

Warunis (*Chem. Ztg.*, 1910, **34**, 1285; *J. Amer. Chem. Soc.*, 1911, A, 1244) employs a method somewhat similar to the Liebig method. In a silver crucible 0·2 to 0·4 grams of the substance is mixed intimately with a mixture of 10 grams finely powdered potassium hydroxide and 5 grams sodium peroxide. The crucible is gently heated and the melt kept liquid for some time. The cooled melt is extracted with water, acidified with hydrochloric acid, a little bromine added, and the liquid boiled to expel bromine and the sulphuric acid estimated as barium sulphate.

Latshaw (*J. Assoc. Official Agr. Chem.*, 1921, **5**, 136-8; *J. Amer. Chem. Soc.*, 1922, A. **16**, 576, 3349; and *J. Amer. Chem. Soc.*, 1923, A. **17**, 2923)

has determined the sulphur content of seeds and feeding stuffs, and has made comparative tests on three methods—

(*a*) The Parr peroxide bomb method, in which the substance is burnt in a bomb with sodium peroxide.
(*b*) A method employing magnesium nitrate as an oxidising agent.
(*c*) The official method in which the substance is fused with a mixture of sodium carbonate and sodium peroxide, in a nickel crucible over a sulphur free flame.

All three methods gave satisfactory results, and Latshaw recommends the use of the magnesium nitrate method owing to its ease of manipulation and accuracy. Trotman and Bell (*supra*), working on wool, were unable to obtain satisfactory results employing the magnesium nitrate method.

Kaye and Sharp (*India Rubber J.*, **44**, p.1189; *J. Amer. Chem. Soc.*, 1913, A., p. 1106) use the following method for the determination of sulphur in rubber, and suggest the extension of the method to organic substances in general. A suitable amount of the finely divided sample is weighed into a porcelain crucible, and mixed intimately with eight times its weight of pure zinc oxide and four times its weight of potassium nitrate. The mixture is covered with a thin layer of zinc oxide and gently heated. When the mixture reacts the flame is removed till the action has subsided. The crucible lid is then removed, and the contents strongly heated for about five minutes. The whole is allowed to cool, the melt extracted with hot dilute hydrochloric acid, the crucible and lid removed from the heater, the contents of which are filtered and sulphuric acid estimated as barium sulphate.

Abderhalden and Funk (*Z. Physiol. Chem.*, **58**, 331; *J. Amer. Chem. Soc.*, 1909, A., 2009) have used the sodium peroxide method for the determination of sulphur in urine. The urine is evaporated down with sodium carbonate and lactose, and this residue mixed with sodium peroxide and fused.

Barlow (*J. Landw*, 1903, **51**, 289-313; and *J. Chem. Soc.*, 1904, **85**, A. ii., 82) uses a combustion method for estimation of sulphur in organic substances. The substance is heated in a combustion tube, first in a current of carbon dioxide and then in oxygen, the gases being passed over heated soda quartz (prepared by mixing sand with 3 to 4 grams sodium carbonate dissolved in water and drying) in the front part of the tube, the end of which is drawn out and turned down to dip into a beaker of water. At the end of the combustion the soda ash, asbestos, &c., are emptied into a dish into which the tube is rinsed with water and dilute hydrochloric acid. The liquor is evaporated to dryness, heated at 110° C., and the residue extracted with dilute hydrochloric acid. The sulphuric acid is precipitated as barium sulphate in the usual manner. The method is stated to give very exact results.

Feigl and Schorr (*Z. Anal. Chem.*, 1923, **23**, 10-29; *J. Chem. Soc.*, 1923, A ii., 784) heat the substance with twice its weight of a mixture of equal parts of sodium carbonate and potassium permanganate under a layer of the same mixture in an iron crucible for one hour at a low red heat. The mass is extracted with aqueous alcohol and the sulphur estimated as barium sulphate.

Schreiber (*J. Amer. Chem. Soc.*, 1910, **32**, 977-85) uses a method involving oxidation by magnesium nitrate. The material is mixed in a nickel crucible with a solution containing sodium nitrate and sodium hydroxide (use for

a 1 gram. sample 10 ccs. of a solution containing 100 grams of sodium nitrate and 150 grams sodium hydroxide per 500 ccs. of solution), 5 grams of crystallised magnesium nitrate are added, the mass well mixed and carefully evaporated to dryness, and eventually strongly heated. The mass is dissolved out with dilute hydrochloric acid, the solution filtered and precipitated with barium chloride. The method is said to agree to within 0·1% with the peroxide and the combustion method of Barlow (*supra*).

Hutin (*Ann. Chim. Analyt.*, 1915, **20**, 214; *J. Soc. Chem. Ind.*, 1915, p. 1105) uses a modified Schreiber method for the estimation of sulphur in rubber. The sample is decomposed by an excess of nitric acid, the liquid evaporated to a syrup, made alkaline with sodium hydroxide and mixed with calcined magnesia to form a stiff paste, which is carefully dried and ignited cautiously. After ignition the residue is dissolved in hydrochloric acid and the sulphur precipitated as barium sulphate.

Stevens (*Analyst*, 1918, **43**, 377) also uses a modified Schreiber method for the estimation of sulphur in rubber. The sample is digested with nitric acid and a little potassium chlorate. The mixture is refluxed for a few hours, evaporated to dryness, and mixed with pure magnesium nitrate. The mixture is carefully heated, and unburnt carbon is destroyed by digestion with nitric acid and potassium chlorate and excess nitric acid removed. The residue is treated with strong hydrochloric acid, evaporated to dryness, and sulphuric acid precipitated as barium sulphate.

The Denis-Benedict Method (Benedict, *J. Biol. Chem.*, 1909, VI., 363; and Denis, *J. Biol. Chem.*, 1910, VIII., 401).—The method was introduced by Benedict for the estimation of sulphur in urine, the urine being evaporated down with a suitable amount of a solution containing copper nitrate and sodium or potassium chlorate, and subsequently ignited. Denis modified the method by using a solution containing copper nitrate, sodium chloride and ammonium nitrate. The residue is dissolved in dilute hydrochloric acid, and the sulphate estimated as barium sulphate.

Trotman and Bell (*supra*), in estimating the sulphur in wool modify the method as follows—The wool is warmed with a little sodium hydroxide solution till it has just dissolved. A few drops of bromine are added, and after a few minutes the solution is neutralised with nitric acid, the Benedict-Denis reagent added, and the estimation continued as described above.

Halvesson (*J. Amer. Chem. Soc.*, 1919, **41**, 1494) has modified the Denis-Benedict method for the estimation of sulphur in fæces, foods, &c. The sample is heated in a Kjeldahl flask with water, and afterwards with nitric acid till the solution is clear. At this stage the residue is treated exactly as in the Denis-Benedict method.

Methods not Involving the Fusion or Ignition of the Substance

White (*Proc. S. Dak. Acad. Sci.*, 1919, **3**, 43; and *J. Amer. Chem. Soc.*, 1920, A **14**, 1760) estimates the sulphur in wool by digesting the wool with a mixture of sodium hydroxide and lead acetate. The mixture is acidified with acetic acid, and the precipitated lead sulphide is collected. The lead sulphide is decomposed and the lead finally estimated as chromate.

Osborne (*J. Amer. Chem. Soc.*, 1902, **21**, 140) has worked upon the method and has shown that in general the results obtained by the White method are too low, a result to be expected.

Gill and Grindley (*J. Amer. Chem. Soc.*, 1909, **31**, 52), for the determination of sulphur in urine, reject the sodium peroxide fusion method of Folin

(*J. Biol. Chem.*, **1**, 157), and employ a method involving oxidation with fuming nitric acid and potassium nitrate, the oxidation being carried out in a Kjeldahl flask. They arrive at the conclusion that in general fusion methods are incorrect, the fused residue often evolving hydrogen sulphide when acidified. Other workers have used as additions to nitric acid for oxidation, potassium chlorate, bromine perchloric acid, &c., and for details of these methods reference may be made to the paper of Trotman and Bell (*supra*).

The Carius Method.—This method is well known, and is in general use for the determination of many elements, other than carbon, hydrogen, and nitrogen, present in organic compounds. The method is simple, and consists in heating the substance under pressure in sealed tubes with nitric acid, when oxidation ensues. It has been subjected to many modifications, almost all of which have been designed to eliminate the use of sealed tubes.

Advantages of the Carius Method

The method avoids the addition of many salts used in other methods, and therefore avoids the risk of the contamination of the barium sulphate precipitate. It is easily controlled, and after the sealing of the tubes and the initial gradual heating to the desired temperature it requires no attention. At no stage of the process is there a risk of contamination of sulphur from gas burners, as exists in all processes where metal crucibles have to be heated for lengthy periods. The only disadvantage of the Carius process (apart from the labour involved in making sealed tubes) is the fact that the glass is liable to be attacked with formation of silicates with subsequent contamination of the barium sulphate precipitate by silica.

Rupp (*Chem. Ztg.*, **32**, 984; *J. Amer. Chem. Soc.*, 1909, A, p. 296) advocates the addition of barium nitrate to the Carius tube. The barium sulphate formed contaminated with more or less barium nitrate* is washed out off the tube into a beaker, boiled up with water, and collected on a filter.

Anelli (*Gazzetta*, 1911, **41**, I. 334; *J. Amer. Chem. Soc.*, 1911, A. 1379) showed that in the ordinary Carius estimation silica is found with the barium sulphate, this leading to high results. The use of barium nitrate in the Carius tube is advocated.

In the determinations given below, no addition of barium nitrate was made to the Carius tube, but the amount of silica in the barium sulphate was estimated and found to be only ·08%, and therefore the sulphur content of wools in the work described is influenced to less than 1 part in 1,200 by this factor.

PREPARATION OF THE WOOL

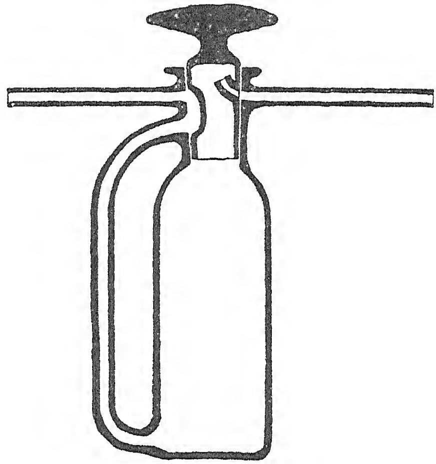
The wool was treated with sulphur-free benzene, worked about for some time, and the hard fatty portions which are sometimes present opened out as much as possible. It was withdrawn from the benzene, well squeezed out, and allowed to dry in warm air. The wool was now hand-sorted to remove the greater portion of foreign matter, a somewhat tedious process but essential to ensure complete removal of all vegetable and other foreign matter from the wool. The sorted wool was now extracted two or three times with pure benzene to remove all remaining grease, and then allowed to dry as before. At this stage it was again hand-sorted, and finally was given a scour in very dilute saponin solution, well washed off in distilled water, and left to dry in warm air. The samples were transferred to the humidity room and

* Evaporation to dryness with hydrochloric acid, to remove nitric acid, appears desirable at this stage.

kept in wire cages for a few days to condition equally. The above method of purification was adopted so as to ensure as little change as possible in the natural condition of the wool.

Method Used for Determination of Moisture Content

In estimating the sulphur content of wool it is essential to know the moisture content of the wool at the time it is taken for the sulphur determination. All sulphur determinations were carried out in duplicate, and a moisture content determination made at the same time. Two samples of wool (about 0·5 grams of wool per sample) were weighed out in small weighing



bottles for the determination of the sulphur, and at the same time a third weighed sample was taken in the special bottle described below.

The special bottle* (see diagram) used for this determination was designed so that with one position of the tap a current of air could be drawn through the wool, entering at the bottom of the bottle, and on turning the tap through 90° the bottle was completely closed. The use of a bottle of this type capable of giving accurate values for moisture content with quantities of wool down to 1 gram was necessary owing to the fact that many of the samples were small—too small, in fact, for use in an ordinary conditioning oven, which requires at least 20 grams of wool.

The bottle containing the weighed wool sample was placed in an electrically heated oven kept at 104° to 106° C., and a current of dry air, dried by means of the usual drying agents (sulphuric acid and calcium chloride) was passed through. After 1½ to 2 hours the tap was closed and the bottle transferred to a desiccator for half an hour and then weighed. The bottle was reheated for half an hour and its weight taken. This was repeated until the weight was constant, and in almost all cases two reheatings were sufficient, and in many cases only one reheating was found to be necessary.

Discrepancy in Dry Weight from Above Method and Conditioning Oven

In checking this method for the determination of moisture content against the method used in commercial practice, i.e., drying out wool in a conditioning oven at about 235° F., it was shown quite conclusively that the percentage regain as determined by the bottle method came out higher

* This bottle was supplied by Messrs. Standley, Belcher & Mason.

than that found with the conditioning oven, the difference being about 1%, for example, 15% in place of 14%. Passing undried air through the bottle gave a regain intermediate between the values obtained with the conditioning oven, and the dry air bottle method.

A fuller investigation will be made in the Physics Department of the Association.

In this paper the regains refer to the dry weight obtained in a current of dry air at 104°-106° C., and not to that from the ordinary conditioning oven.

REGAIN OF KEMP

It is interesting to note the equal regain shown by kempy and non-kempy portions of the same fleece, both with Blackface wool and Turkey mohair. The black face was separated by hand sorting into three fractions, which may be called

(*a*) Fine non-kempy fibres.
(*b*) Coarse kempy fibres.
(*c*) Kemps.†

All three fractions were placed in the humidity room, and samples from (*a*) and (*b*) were bottled simultaneously both for sulphur and for regain determinations. The regain of (*a*) and (*b*) were almost identical, being—

Fine non-kempy fibres ...	15·66%
Coarse kempy fibres ...	15·62%

and on the evidence of these determinations the kempy fraction was assumed to have a regain of 15·62%.

In the case of mohair the regains are as follows—

Fine mohair	15·64%
Coarse mohair	15·68%

Details of the Sulphur Determination

About 3 ccs. of fuming nitric acid (s.g.=1·53) were transferred by means of a long funnel and pipette to the bottom of a Carius tube, and wool transferred by means of forceps and pushed down the tube to within about 6 inches of the bottom by means of a glass rod. The tube was sealed in the usual manner, and estimations were carried out in duplicate for each wool. The tubes were heated together in the Carius furnace, and in a period of about 1½ hours the tubes were raised to 200° C. and maintained at this temperature for eight hours. Each tube was allowed to cool overnight and opened by softening the tip with a Bunsen flame, a slight pressure being found in the tube. After withdrawing from the furnace and cutting off the ends, the tubes were gently warmed to drive off dissolved gases, and the contents were washed out into beakers, evaporated to dryness (on steam) with the addition of hydrochloric acid, this being repeated to remove all traces of nitric acid, which is detrimental to the sulphate estimation. About 100 ccs. of hot distilled water were added, and the contents filtered off to remove any traces of glass introduced when opening the tubes. The liquid, about 400 ccs. in volume, was acidified with dilute hydrochloric acid, heated to boiling and precipitated by the slow addition of 50 ccs. of boiling N/20 barium chloride. After keeping hot for some hours and allowing to stand overnight, the barium sulphate was collected and estimated on a weighed Gooch crucible in the usual way.

† The reason a regain determination was not carried out on "(*c*)" was that only about 0·5 gram of the sample was available, a very large amount of Blackface having to be sorted to obtain this amount.

It should be especially noted that to ensure complete breaking up of the wool it is essential that the temperature of the tubes be not less than 200° C., and further that only a short length, at the most one inch of the tube, project beyond the iron containing tube. In one or two cases when these conditions were not observed, on opening the tubes a smell of oxy-butyric acid was observed, and when washed out the contents of the tube formed a yellow solution, and usually a low result for sulphur content was obtained. Results from any wool showing a difference in sulphur content in two determinations of above 1 part in 100 were rejected and the analyses repeated.

The sulphur content of between 40 and 50 wools has been determined, the following table showing some of the typical results. The lowest value found for sulphur content is that for coarse mohair, the value being 3·03%. The highest value found is that of 4·13% for a wool from a Welsh mountain sheep, this being one of a series of nine wools examined.

It is proposed in a subsequent paper to deal with the qualities of wools, in relation to their sulphur content, but it may at once be remarked that the lowest values of sulphur content are found with coarse wools (*cf.* following table).

Table of Typical Results

Type of Wool.	%'s of Sulphur found I.	II.	Regain	%'s of Sulphur on Dry Weight	Remarks
Australian merino, 100's	3·25	3·21	16·44	3·76	
Lamb's wool merino ...	3·20	3·19	16·76	3·73	
Lincoln (white)	2·67	2·68	15·89	3·10	Two samples from different fleeces, one fleece very yellow, other fairly white.
Lincoln (yellow)... ...	2·77	2·79	15·95	3·26	
Turkey mohair (fine) ...	2·89	2·92	15·64	3·36	The mohair was separated by hand sorting into two fractions.
Turkey mohair (coarse)	2·62	2·63	15·68	3·03	
Fine Ripon fleece ...	2·85	2·87	16·74	3·34	
Peruvian (1924) ...	3·23	3·21	16·47	3·75	Samples from the same sheep, clipped one year apart.
Peruvian (1925) ...	3·30	3·27	16·19	3·82	
Monte Video (Romney)	3·22	3·19	17·44	3·76	
Blackface Fine ...	3·29	3·31	15·66	3·82	Blackface was hand sorted into three fractions. The regain of the kempy fraction was taken as 15·62, i.e., equal to the regain of the coarse fraction.
Blackface Coarse ...	2·88	2·88	15·62	3·33	
Blackface Kempy ...	2·80	—	(15·62)	3·24	
Welsh mountain P. 64 ...	3·35	3·34	18·65	3·97	Two typical analyses from a series of analyses made on Welsh mountain sheep; the S's are the first clip and the P's the second clip.
Welsh mountain S. 71 ...	3·20	3·21	18·28	3·79	
Cape merino (Kaffrarian)	3·45	3·41	16·47	4·00	
Cape merino (Le Grange).	3·37	3·40	16·32	3·94	

A striking example of how sulphur content varies in different parts of the same fleece is to be found in the case of the black face wool. The wool

was separated by hand sorting into three fractions and the sulphur content of each fraction determined.

	% of Sulphur
Fine non-kempy wool	3·82
Coarse kempy fibres	3·33
Kemps	3·24

A similar result was obtained with Turkey mohair, the sulphur contents of fine and coarse fractions from the same sample being 3·36 and 3·03 respectively. The extreme values found in the 20 Australian pedigree wools examined were 3·46% and 4·11%, the mean value being 3·78%. The Welsh wools examined show variations between 3·75% and 4·13% in sulphur content, the mean value being 3·94%. It is of interest to note that the average sulphur content of the Welsh wools from the first shearing is 3·83%, whereas from the second shearing the value is 4·03%. Too much stress cannot be laid upon these figures owing to the comparatively small number of samples worked upon, but it is intended to follow up this question by examining samples of wool from the same sheep over a period of years; in addition the sulphur content in relation to a number of other factors is being investigated.

37—THE MICROSCOPICAL EXAMINATION OF DAMAGED COTTON HAIRS BY THE CONGO RED TEST AND THE SWELLING TEST OF FLEMING AND THAYSEN

By THOMAS BINSTEAD BRIGHT, B.A.
(British Cotton Industry Research Association)

INTRODUCTION

During the course of investigations of the fine structure of the cotton hair, Miss G. G. Clegg, working in this laboratory, observed that hairs which had been swollen in sodium hydroxide and then stained in Congo Red did not become uniformly coloured, but took up the stain more intensely at points where the cuticle had become loosened or totally detached, and that this staining afforded a ready means of detecting damage to the cuticle. A method based upon these observations has now been worked out, and the present paper describes its application in determining microscopically the visible signs of damage in a Sakel cotton resulting from treatment in various ways, e.g., by heat, by mechanical means, by the action of a fungus, or by the action of acid. The method is shown to be capable of detecting even the slightest mechanical damage, and reveals in characteristic form the effect of heat or the attack of a fungus, though it is doubtful whether in all cases the last two effects could be distinguished one from the other. The changes brought about in cotton hairs by treatment in the cold with sulphuric acid of varying concentration are shown to be of a different nature from the other forms of damage investigated.

For the present work one cotton, a good quality Sakel, was used throughout, being examined in the undamaged state and after infliction of damage in varying degree under controlled conditions in the laboratory.

The only method which has so far been developed to reveal modifications of hair structure due to attack by micro-organisms and the probable resulting amount of deterioration ("tendering") is the swelling test of Fleming and Thaysen[6]. The conclusions of these workers have met with some adverse criticism, chiefly from Denham[3] and Burns[1], so the opportunity was taken to apply both the Congo Red test and the swelling test to similarly treated samples of the same cotton, and to compare the results. As an outcome, no general statement can be made about the performances of the two tests; their relative efficiencies vary according to the material on which they are used, and each case must be considered separately, bearing in mind the type and degree of damage that is being investigated.

THE METHOD OF APPLYING THE CONGO RED TEST AND THE RESULTS TO BE OBTAINED THEREFROM

About 0·1 gram of the cotton was placed in a filter flask of water, and as much air as possible withdrawn by means of the filter pump. This ensured that the cotton was thoroughly wetted out. It was then gently squeezed to remove most of the water, placed in 25 ccs. of an 11%* solution

* The use of solutions of exactly the right concentration is a matter of some importance. All solutions were made up more concentrated than actually required, and were then adjusted to the correct specific gravity, as obtained from the tables in the *Chemists' Year Book*. The percentages refer to grams per 100 grams of solution.

of sodium hydroxide, shaken thoroughly, and allowed to stand for five minutes. After washing rapidly in water, it was placed in a saturated (=about 2%) solution of Congo Red, and shaken at intervals for six minutes, when it was removed and washed by shaking up in water, the latter being changed until it no longer became pink. With as little delay as possible the cotton was placed in 18% sodium hydroxide, teased out, and a few hairs mounted in the same liquid for examination under the microscope. To prevent any of the sodium hydroxide escaping, the coverglass was sealed down with the cement recommended by Langeron[5]. The examination was made with $\frac{2}{3}$ in. objective and a $\times$10 eyepiece, the iris diaphragm of the substage condenser being left wide open so as to fill the back lens of the objective with light.

A normal undamaged cotton hair, on being placed in 11% sodium hydroxide, swells nearly to its full extent, as described by Calvert and Summers[2], and its irregular cross section changes to an ellipse. The cuticle, however, remains intact and, later, takes up the Congo Red to a slight extent only, becoming coloured a faint pink. Finally the 18% sodium hydroxide swells the cellulose of the hair still further, and in places actually bursts the cuticle, thus exposing to view a strip of white cellulose. The colour contrast between the pink and the white is by no means great, but can be seen in several hairs in Fig. 1. Where cotton has been damaged by mechanical means, the cuticle is cut or at least weakened at the point of damage. On application of the Congo Red test, the cellulose is exposed or may even protrude, and becomes deeply stained, giving the appearance of a bruise upon the hair. If the cotton has been damaged by exposure to heat, sulphuric acid, or the attack of a fungus, the appearance is different, and in each case more or less characteristic, as described in detail below.

An outstanding difficulty in the detailed examination of any cotton was encountered, namely, the large variation amongst the individual hairs. For the purpose in hand it was only necessary to consider one character, this being the amount of secondary cellulose laid down in the hair wall, for the variation in this was one of the only causes so far investigated of the difference in behaviour of cotton hairs in a swelling solution.[2] In most commercial cottons there were a certain number of fuzz hairs, which though short in length were extremely thick-walled. The lint hairs themselves varied considerably in this respect, ranging from hairs of large cellulose development down to thin-walled hairs almost devoid of thickening. If the cotton under examination by the Congo Red test contained any hairs with abnormal cellulose development, particularly fuzz hairs, the swelling in the weaker (11%) sodium hydroxide was generally sufficient to rupture the cuticle. In this case the cellulose bulged out, and during the treatment with Congo Red became deeply stained. Since the cuticle usually split in a line running spirally round the hair, the red band which appeared after the application of the Congo Red test followed this course (Fig. 2), and an examination with a high power objective showed the torn edge of the cuticle flanking this band. These spiral bands had previously been observed in hairs under somewhat similar treatment by other workers, notably Denham,[4] but their real character had not been described. Their occurrence did not necessarily indicate damage, but simply the presence of hairs with an extreme development of cellulose. When using the test to examine a cotton containing hairs of this type, it was found advisable to reduce the concentration of the sodium hydroxide in the preliminary swelling from 11% to 9%.

This gave a preparation consisting of hairs all stained faintly pink and free from spiral bands. On the other hand, if the cotton contained any hairs with less than the normal development of cellulose, these hairs took up the Congo Red evenly, but to a greater extent than normal ones. In extreme cases where the hair was immature in development and the wall very thin, deep red staining took place throughout, and the ribbon shape with convolutions was retained. Since nearly all cottons were found to contain a certain number of abnormal hairs, the appearance which these displayed after being treated by the Congo Red test had to be noted in order to avoid interpreting them as signs of damage.

The technique is simple to carry out if the cotton to be examined is at the most slightly damaged, for the hairs become entangled during the first swelling and can be transferred from one solution to another by means of a glass rod. But in a badly damaged sample the hairs are easily broken into small pieces, which become dispersed when the solutions are shaken, and are usually left behind during transfer from one liquid to another. However, in these circumstances loss can be avoided by filtering through glass-wool.

Material

In order to avoid the complications raised by the presence of so many types of hair, search was made for a cotton as free as possible from very thick- or thin-walled hairs. The cottons available for use were examined by the Congo Red test, and the one which appeared most satisfactory in this respect was a Sakel, grown in 1923 on the Egyptian State Domains Seed Farm, and forwarded to this laboratory as a representative sample. The total quantity available was about one pound, from which an experimental sample was collected by taking small bunches and drawing from each of these in turn a few groups of twenty or thirty hairs. To divide up these groups the whole of the experimental sample was then thoroughly mixed and test samples finally obtained by drawing small groups of hairs from different parts of the whole. Except in one or two cases where it is specially stated, this material was used throughout, and appears in all the illustrations.

Description of Results Obtained

"*Damage-free Cotton.*"—This description was reserved for cotton which after treatment by the test showed no sign of damage. A cotton which fulfilled this condition was obtained from some specially chosen bolls of Punjab-American-285F. All the hairs were stained pink, and deep red staining was completely absent except at the end of each hair where this had been torn from the seed, and where naturally mechanical damage had taken place, giving the Congo Red immediate access to the cellulose. Any ruptures of the cuticle due to the final swelling in 18% sodium hydroxide showed as faint white stripes on the pink of the outside. Damage done during teasing out on the microscope slide was easily recognised by the absence of any red staining of the exposed cellulose (Fig. 5).

"*Commercial Undamaged.*"—Under this heading were included cottons that had been ginned and baled, as in ordinary commercial practice. In the case of the Sakel, most of the hairs were pink (Fig. 1), but a few showed bruises, and hairs which tapered at the end usually appeared as shown in Fig. 3. An occasional thick-walled hair showed broad spiral bands as in Fig. 2.

Mechanically Damaged Cotton.—This term was applied to two samples of the Sakel which had been subjected to mechanical damage in a mortar. Fig. 4 shows small bruises upon a hair that had been slightly damaged by being tapped gently with the pestle, and in Fig. 6 can be seen more extensive bruises. Fig. 7 shows the result of grinding up with great force; the bruises were so large and numerous as to cover almost the entire surface of the hairs, so that these appeared deeply stained and very ragged after the application of the test.

Heat Damaged Cotton.—This had been exposed to a temperature of 110° C. in an electrically heated thermostatic oven. It was found that the manner of exposure influenced the final result. If the sample was left between sheets of filter paper in a closed Petri dish for as long as six days the only sign of damage was the appearance of simple spiral bands in occasional hairs (Fig. 18). If, however, the cotton was freely suspended in a loop of asbestos string, 24 hours exposure was sufficient to produce spiral bands, either simple or multiple, in about 20% of the hairs. The regularity of the bands and the number of hairs possessing them increased with the time of exposure, until after a fortnight in the oven all the hairs were covered with multiple spirals. To obtain higher temperatures a small gas-heated oven was used, the cotton being again suspended in a loop of asbestos string. After four hours at about 150° C. it had become yellowish, and the Congo Red test showed that some of the hairs were covered with fine multiple-spiral bands, which displayed very clearly the points of reversal of the spiral (Fig. 19). Others, which were also spirally marked though less distinctly, were not swollen to the rod shape, but remained as ribbons with a corrugated outline (Fig. 20). Pronounced singeing was caused by exposure to a temperature of 190° C. for a similar period, and in such cases the hairs became stained red throughout, but again could not be swollen to the rod shape, remaining as ribbons with a corrugated outline and deep cracks. In some cases the cuticle could be seen as a wrinkled yellow ribbon wound spirally round the hair (Fig. 21). To test the effect of steam heat, the cotton was pushed about half way down a test tube, which was then plugged with bacteriological cotton wool, and the whole exposed to 15 lbs. per sq. in. steam pressure in an autoclave for 15 minutes. No sign of damage could be detected by means of the test, the hairs being free from any red staining.

Cotton Damaged by the Attack of a Fungus.—This cotton had been sterilised, inoculated with the spores of a fungus, and incubated at 25° C., some sterilised distilled water being added. The first fungus employed was a strain of *Aspergillus niger*, one of the commonest infections of raw cotton. The test showed evidence of damage to all the hairs, which in some places were stained evenly red (Fig. 16) and in others were covered with multiple spiral bands, similar to those produced by a temperature of 150° C. Cracks and abrasions, however, were totally absent. The second fungus, which still awaits identification, was employed on account of its great capacity for attacking the cotton hair and penetrating the central canal, or lumen. In this case the hairs were stained red throughout, broken up into short lengths, and covered with cracks and abrasions (Fig. 17).

Cotton Damaged by Sulphuric Acid.—The breaking loads of single hairs of Egyptian cotton after treatment with different concentrations of sulphuric acid in the cold had been determined by Vincent[9], so in order to find out to what extent the Congo Red test could indicate a decrease in strength due

to the action of sulphuric acid, this author's method of treatment was followed. The cotton was first wetted out under the filter pump, and then placed in about 200 ccs. of the acid solution; the whole was thoroughly shaken and allowed to stand for 48 hours. The cotton was then washed thoroughly in water and dried slowly in air. It was found that concentrations of acid up to 30% (=grams per 100 ccs. of solution) produced no effect that could be readily detected by the Congo Red test, but hairs that had been treated with 40% acid were covered with irregular red streaks and patches, quite different in appearance from the regular spiral bands produced by heat, or the swollen bruises found in cases of damage by mechanical means. In addition, the hairs were not fully swollen to the rod shape, but remained corrugated. These effects became more marked as the concentration of the acid was still further increased (Fig. 8).

THE SWELLING TEST OF FLEMING AND THAYSEN

The original microscopical test for damage to the cotton hair, developed by Fleming and Thaysen[6], the pioneer workers in this field, was based upon experiments by Balls with the viscose process of Cross and Bevan. Their method was employed to estimate only the damage caused by microorganisms, this term being used to denote bacteria and the streptothrices, which are intermediate between the true bacteria and the fungi, resembling sometimes one, sometimes the other, according to conditions. The cotton to be tested was swollen in a mixture of carbon disulphide and 15% sodium hydroxide, and examined under a low magnification, the damaged hairs being counted against the undamaged ones, and the count expressed as a percentage. In the present investigation some difficulty was experienced in carrying out the counts, but through the courtesy of Dr. Thaysen a visit was paid to the laboratory at Holton Heath and the points of misunderstanding were cleared up. For example, it must be noted that for the purpose of the count that portion of a hair in the field of the microscope at any one time was reckoned as one unit, so that a single complete hair figured in the count as several units, some of which might be classified as damaged and others as undamaged. It would appear that Burns[1] also misunderstood this method of making the count, and was thus led to criticise the test.

In the course of the work now described it was found that on placing a cotton hair in a mixture of 15% sodium hydroxide and carbon disulphide, the cellulose immediately expanded, inwardly to fill up the central canal, and outwardly to stretch the cuticle to its elastic limit. The reaction was complete in two or three minutes, and no further change occurred until, after about half an hour, the stress imposed by the expanding cellulose became sufficient to burst the cuticle. The line of rupture was a spiral one round the hair, so that the cuticle became rolled back upon itself to form a tightly stretched cord, which moulded the cellulose into a shape resembling either a chain of beads (Fig. 11) or a corkscrew (Fig. 13). The stages illustrated were only reached after swelling for about an hour, though the time required varied according to the type of hair and the amount of shaking applied. Further extension of the time of swelling caused the cellulose to dissolve at the edges, so that the general outline of the hair grew faint and ragged. If the test was applied to a hair with a cuticle that had been split or loosened, the cellulose, being no longer restricted at this point, expanded very rapidly and soon began to dissolve. The appearance presented by such a hair depended naturally on the length of time that it had been in

the swelling mixture; if the time was short, say less than half an hour, the undamaged portions of the hair were still free from beads, whilst an irregular bead was formed at the point of injury to the cuticle. A longer period of swelling resulted in the cellulose at this point going into solution and producing a break in the hair. Thus, slight mechanical damage, such as the Congo Red test had shown to be present in commercial cottons, was not easily recognisable as such under the conditions of the swelling test, but nevertheless its effect was present. Severe mechanical damage, on the other hand, as produced by grinding in a mortar, not only tore the cuticle but also lacerated the cellulose, leaving cracks which were plainly visible after swelling for, say, 20 minutes (Fig. 10). Longer exposure to the swelling mixture proved to be inadvisable, for many of the hairs began to dissolve, so that little could be learnt as to their condition; this was found to hold good for damage due to any of the causes investigated; indeed, an unduly prolonged period of swelling gave misleading results, the more badly damaged hairs dissolving and leaving only the less damaged ones to come up for examination.

The samples of the Sakel cotton referred to above (page 144) that had been attacked by fungi in pure culture, were also submitted to the swelling test. The hairs that had been exposed to the action of *Aspergillus niger* swelled evenly and without forming beads, but displayed spiral striations (Fig. 15) obviously corresponding to the multiple spiral bands produced in the same cotton by the Congo Red test. It seemed doubtful whether, in the absence of beading, these hairs should be classed as damaged, or, in the absence of any obvious surface injury, as undamaged. Dr. Thaysen expressed the opinion that no hair-portion should be counted as damaged unless it displayed definite cracks or abrasions. This sample therefore passed the swelling test as undamaged. In the second sample, that had been exposed to the lumen-invading fungus, surface damage was widespread (Fig. 14), very few hair-portions being fit to be counted as good. It was noted, however, that the injuries of some of the hairs resembled those produced by grinding almost to the point of being indistinguishable (Figs. 10 and 12), so that it would seem advisable to use the swelling test only on cottons known to be free from mechanical damage unless very slight.
